Abstract

Mesenchymal progenitor cells, a multipotent adult stem cell population, have the ability to differentiate into cells of connective tissue lineages including fat, cartilage, bone and muscle, and therefore generate a great deal of interest for their potential use in regenerative medicine. During development endochondral bone is formed from a template of cartilage that transforms into bone, however, mature articular cartilage remains in the articulating joints where its principal role is reducing friction and dispersing mechanical load. Articular cartilage is prone to damage from sports injuries or ageing which regularly progresses to more serious joint disorders such as osteoarthritis (OA). OA is a degenerative joint disease characterized by the thinning and eventual wearing of articular cartilage, and affects millions of people worldwide. Due to low chondrocyte motility and proliferative rates, and complicated by the absence of blood vessels, cartilage has a limited ability to self-repair. Current pharmaceutical and surgical interventions fail to generate repair tissue with the mechanical and cellular properties of native host cartilage. The long term success of cartilage repair will therefore depend on regenerative methodologies resulting in the restoration of articular cartilage that closely duplicates the native tissue. For cell-based therapies, the optimal cell source must be readily accessible with easily isolated, abundant cells capable of collagen type II and sulfated proteoglycan production in appropriate proportions. Although a cell source with these therapeutic properties remains elusive, mesenchymal chondroprogenitors retain their expansion capacity with the promise of reproducing the structural or biomechanical properties of healthy articular cartilage. As current knowledge regarding chondroprogenitors is relatively limited, this review will focus on their origin and therapeutic application.

Introduction

Osteoarthritis (OA) is a chronic disease of the joints characterized by progressive destruction of articular cartilage resulting in painful, limited joint movement. In the European Union over 39 million people exhibit symptoms of OA, a number anticipated to double in the next decade, creating an imperative for the timely development of effective treatments for the disease [1]. Current clinical therapies such as pharmaceutical interventions, bone marrow stimulation techniques or microfracture do not result in regeneration of healthy cartilage tissue [2-3], but focuses on the short-term relief of OA symptoms. When pharmaceutical intervention fails, clinicians regularly revert to invasive and permanent solutions.

The first widely accepted regenerative treatment for cartilage repair was autologous chondrocyte transplantation. Despite its initial therapeutic promise, chondrocyte transplantation has associated complications such as donor site morbidity, repair cell de-differentiation with expansion *in vitro* and restricted cellular life span upon implantation [4]. Immature progenitor cells with the potential to develop into mature tissues in response to appropriate cues have therefore become a primary focus of cartilage repair strategies as an alternative to chondrocyte-based methods [5].

The application of chondroprogenitors, cells that are specifically pre-disposed to differentiate into mature chondrocytes, to repair articular lesions and subsequently inhibit the onset of OA is a current focus of research efforts. As the mature articular joint develops from embryonic mesodermal precursors that differentiate into chondroprogenitors and ultimately into mature adult chondrocytes or synoviocytes, it is hypothesized that progenitors retained in these adult articular tissues provide a potential reservoir of chondroprogenitors.

Development of the Chondroprogenitor

The development of the embryonic appendicular skeleton, whereby undifferentiated limb mesenchyme matures into a cartilaginous precursor and subsequently into bone, is dependent upon precursor exposure to specific combinations of morphogens and mechanical stimuli. Presumably a residual chondroprogenitor in the adult has been similarly primed and, when further stimulated, will respond by undergoing chondrogenic differentiation. Of critical importance during this developmental process are the TGF- β , FGF, Wnt and Notch signaling pathways.

In embryonic limb development, fibroblast growth factor (FGF)-4 stimulates Sonic hedgehog (Shh) expression in a positive feedback loop that coordinates proximal-distal and anterior-posterior patterning of the cartilaginous anlagen, as was historically demonstrated in a avian model [6]. Shh, in turn, initiates a cascade of stimulatory molecules such as those of the TGF- β superfamily, thereby inducing mesenchymal differentiation into chondrocytes as was originally demonstrated in murine limb mesenchyme [7]. Similarly, FGF-18 promotes cartilage formation in murine limb progenitor *in vitro* micromass cultures [8]. This effect is currently under clinical investigation for cartilage repair [9]. This phase I safety study assesses the ability of FGF-18 to stimulate chondrocyte development leading to the repair and regeneration of articular cartilage in patients undergoing knee replacement surgery. As FGF receptor (FGFR) isoform expression is highly regulated during each stage of embryonic human limb chondrogenesis [10], conserved FGFR expression patterns have been identified in embryonic chondrogenesis *in vivo* and progenitor cell differentiation *in vitro*, enabling a mechanism to compare tissue engineered cartilage with natural development [11].

Mesenchymal cell differentiation into chondrocytes, and the associated regulation of ECM deposition, is minutely coordinated by paracrine factors. TGF- β and BMP signalling, often through Sox9 as a transcriptional mediator, are responsible for initiating expression of cartilaginous ECM such as aggrecan, collagens II and XI, fibronectin and tenascin in *in vitro* murine micromass cultures [12-13]. Opposing roles for the involvement of the MAP kinase signaling components ERK-1 and p38 downstream of TGF- β superfamily stimulation have been identified in *in vitro* chondrogenesis[14]; suppression of Erk-1/2 resulted in enhanced chondrogenesis whereas inhibition of p38 suppressed cartilage formation [15]. More specifically, inhibition of p38 significantly repressed formation of pre-chondrogenic nodules *in vitro*, sustained N-cadherin expression and increased expression of fibronectin and $\alpha 5\beta 1$ integrin, while ERK inhibition showed no effect on nodule formation, reduced expression of N-cadherin and accelerated reduction of fibronectin and $\alpha 5\beta 1$ integrin expression during late stages of chondrogenesis [15]. This delicate balance between signaling mechanisms is sustained in mature cartilage ensuring maintenance of a healthy articular tissue [16].

Chondrogenic differentiation of adult human progenitor cells *in vitro* through TGF- β 1 is mediated intracellularly by both Smad3 and Wnt-associated β -catenin [17]. By increasing nodule formation, Wnts 5a and 5b have been shown to promote early chondrogenesis *in vitro* [18] and play an important role in chondrocyte differentiation and proliferation in an *in vivo* mouse model by controlling expression of cell cycle regulators such as cyclin D1 and p130 [19]. However, expression of Wnts 14, 7a and 1 have been demonstrated to inhibit the chondrocyte maturation in *in vivo* chick models and *in vitro* micromass cultures [20].

A distinct population of murine embryonic precursors located at the prospective joint will develop into adult articular cartilage and synovial tissues, in contrast to the remaining cartilaginous template that ossifies to form the appendicular skeleton [21]. As the embryonic development of articular cartilage proceeds from the preliminary cartilaginous template to an articulated joint with striated cartilage and underlying subchondral bone, Notch signaling plays a fundamental role as demonstrated *in vivo* with an avian model [22]. Notch signaling via JAG1 is required to initiate chondrogenesis in adult human progenitor cells *in vitro* [23], however, maintained Notch signaling in adult human progenitor cell micromass cultures suppresses differentiation by inhibiting Sox9 binding of the type II collagen promoter [24], indicating that temporal regulation of Notch signaling is paramount to proper development.

Recent advances indicate a strong association between hypoxia-inducible factors (HIFs) in chondrogenesis and the development of OA. While HIF-1 α stimulates chondrogenic differentiation, HIF-2 α is involved in endochondral ossification and cartilage degradation. Amarilio *et al* inactivated HIF-1 α in mouse limb bud mesenchyme resulting in abnormal joint and cartilage formation *in vivo*, indicating HIF-1 α regulates the differentiation of pre-chondrocytes [25]. Further *in vitro* studies demonstrated reduced cartilage formation in HIF-1 α -depleted micromass cultures and reduced expression of key chondrogenic markers SOX9, SOX6, aggrecan and collagen type II [25]. *In vivo* functional studies by Yang *et al* demonstrated that HIF-2 α is a critical transcription factor which catabolically regulates cartilage degradation through MMP and ADAMTS expression [26].

The delicate balance of paracrine factors discussed above, as well as several other factors not reviewed here, results in the differentiation of an embryonic mesenchymal progenitor cell into a mature articular chondrocyte. Presumably chondroprogenitors residing in the adult have also been primed by these signals and will therefore respond similarly by undergoing chondrogenic differentiation when further stimulated, making them an attractive cell source for the regeneration of cartilage. The successful identification of a pool of chondroprogenitors *in vivo*, followed by their isolation and *in vitro* expansion, is therefore a pre-requisite to their clinical application.

Progenitor Cell Tissue Distribution

Adult progenitor cells have been described *in vivo* and *in vitro* as mobile cells with both differentiation and self-renewal potential that reside in a niche adjacent to mature, differentiated cells [27]. Progenitors have been successfully retrieved from several sources including adipose, synovium, synovial fluid, perichondrium and bone marrow [28] [29] [30] [31] as summarized in Table 1. Depending on the tissue source from which they are isolated, progenitors harbor distinct differentiation potential and occur at variable frequencies.

Efforts by Friedenstein [31] and Pittenger [32] unequivocally demonstrated the presence and potential of bone marrow derived MSCs with the innate ability to differentiate into multiple mesenchymal lineages *in vitro*. Despite their rare occurrence (0.001-0.01% of cells in the stromal compartment [32]), bone marrow derived MSCs may be efficiently isolated and expanded in culture without associated donor site morbidity.

Bone marrow derived MSCs are isolated non-selectively by exposing the mononuclear cell aspiration to tissue culture plastic. Adherent progenitors, termed colony forming unit-fibroblasts (CFU-Fs), initiate the generation of a clonal population of CD105, CD73, CD90 and CD44 positive cells that are then expanded in monolayer [33]. Clonal analysis of bone marrow-derived MSCs describes 20%-50% of the total population of cells to be truly tri-potent, but most importantly has identified a subpopulation of MSCs that retains only chondrogenic potential, or chondroprogenitors [34]. As the resultant population of MSCs is heterogeneous, efforts continue to identify and isolate a homogenous

chondroprogenitor cell population from marrow that would more efficaciously repair diseased cartilage.

Similar to those in marrow, adult periosteal derived multipotent progenitors are tri-potent [35]. Regardless of donor age, periosteal progenitors are clonogenic and have significant *in vitro* expansion potential [36] with continued positive expression of traditional bone marrow-derived progenitor cell markers such as CD105, CD166, CD13, CD73 and D7-FIB [28]. Most importantly, identification of specifically chondro- and osteogenic precursors within the periosteum has been identified, making this tissue an attractive tissue source for chondroprogenitor isolation [37].

The mature synovial membrane is composed of a fibrous external layer and an inner secretory layer that produces synovial fluid. Synovial tissue derived multi-lineage progenitors may have the greatest overall therapeutic potential to regenerate damaged cartilage due to their impressive capacity for proliferation and their superior chondrogenic differentiation potential [38]. Interestingly, during the early stages of OA there is an increase in progenitor cell numbers in synovial fluid, presumably as a result of synovial membrane degradation leading to their release to the synovial fluid [39]. Synovial membrane derived mesodermal progenitors uniquely are not depleted in number or potential with donor age [38] making them an attractive cell source for autologous therapy.

Like synovium and bone marrow, infrapatellar fat pad contains a readily abundant source of CD105, CD44 and CD166 positive progenitor cells with the potential to differentiate into mesodermal lineages. CD271 expression, a putative marker of the *in vivo* progenitor cell [40], is highly expressed in adipose progenitors and is uniquely maintained with proliferation, indicating retention of their progenitor capacity upon expansion [29].

Although healthy mature cartilage is primarily composed of mature chondrocytes, progenitor cells with chondrogenic capacity have been isolated from the superficial zone of articular cartilage [41]. Additionally, chondroprogenitors have been identified in arthritic cartilage after their migration from the bone marrow through breaks in the tidemark and into the diseased cartilage [42]. With two potential sources of progenitor cells, one in the healthy superficial zone and another generated as a repair response to disease, the development of technologies to harness and retain their potential may offer novel regenerative therapeutics.

Progenitor cells have also been identified in tendon specifically in an ECM-rich niche. The tendon derived stem/progenitor cells (TSPCs) are clonogenic with a higher rate of proliferation as compared to bone marrow derived MSCs. TSPCs are multipotent with an enhanced potential for osteo- and adipogenic differentiation as compared to bone marrow-derived progenitors. With diminished chondrogenic potential and proficient tenogenic potential, TSPCs are perhaps best suited for tendon repair applications [43].

Comparison of progenitors derived from adult bone marrow, synovium, periosteum and adipose has demonstrated distinct differences between these cell types [29-30]. Upon initial isolation of progenitor cells, there are significantly fewer CFU-Fs in bone marrow derived cells as compared to progenitors from adipose, periosteum or synovium. Synovial fluid and bone marrow derived progenitor cells share a similar chondrogenic or osteogenic potential [44], however, synovial membrane derived cells in particular retain significant potential for chondrogenesis [38]. Together, these adult tissue sources offer an opportunity to specifically isolate progenitors that when clonally analyzed are predisposed to differentiate into chondrocytes thereby offering a source of highly efficacious repair cells. Figure 1 depicts some possible sources of chondroprogenitors. The increased potential of synovium-derived progenitors may be associated to the proximity of the niche they reside in to articular cartilage. A common embryonic genesis for articular cartilage and synovial tissue may also be a factor [21]. Migration of progenitor-like cells from marrow to OA cartilage has been suggested but not as yet in the healthy joint and the presence of marrow-derived mesenchymal-like progenitors in rheumatoid arthritic pannus highlights an additional route for migration of marrow-derived chondroprogenitors [45]. However, identification of the optimal chondroprogenitor awaits a direct intra-donor comparison of cells isolated from the various sources.

Clinical Considerations and Therapeutic Applications

Articular chondrocytes, when explanted and expanded *in vitro*, lose their chondrocytic phenotype as indicated by morphometric changes and elimination of type II collagen deposition [46]. The re-differentiation of these cells *in vitro* regenerates their articular phenotype while the differentiation of a progenitor cell *in vitro* results in the generation of a transient, pre-hypertrophic chondrocyte, similar to the chondrocyte phenotype in the developing embryonic skeleton [47], highlighting the inherent difference between progenitors and native chondrocytes [48]. Essential to the functional formation of neocartilage through the implementation of progenitors is the acknowledgement of these evident differences in the phenotypic state, and our ability to develop methods to overcome the present gaps. It is crucial that research focuses on not only the signaling events that are known to support chondrogenic differentiation in the embryo but also on the molecular events that fail to initiate in progenitor cell differentiation.

Bone marrow derived MSCs have been directly injected [49] or combined with a scaffold and implanted [50] into the intra-articular space *in vivo* in an effort to assess their potential for efficacious repair of damaged cartilage tissue or diseased joints. These results have proven to be ambiguous and unsatisfactory as a result of low viability and retention of the cells [49]. Due to inconsistency in results and association with hypertrophy and ossification, there are very few human clinical trials investigating heterogeneous bone marrow derived MSCs as a therapeutic for cartilage repair.

The ongoing Chondrogen clinical trial is currently investigating the application of bone marrow derived MSCs to treat meniscal damage and thereby delay the onset of OA. Conducted by Osiris Therapeutics, preliminary reports have claimed a statistically and clinically significant improvement in pain experienced by patients post injury with application of MSCs [51]. The application of Chondrogen was well tolerated by recipients and superior to currently available, comparable products on the market. With advances in chondroprogenitor cell isolation and culture techniques, products such as this will be improved upon by replacing large numbers of perhaps minimally efficacious heterogeneous MSCs with low numbers of highly efficacious chondroprogenitors.

To treat chondral defects, Advanced Technologies and Regenerative Medicine is currently investigating a cartilage autograft implantation system where autologous healthy cartilage is harvested from non-weight bearing regions, minced and re-distributed on a scaffold for implantation. Initial results have been promising, supporting a phase III clinical investigation [52]. If left untreated, lesions such as these regularly result in the onset of OA. It is possible that the reparative cell responsible for the generation of neocartilage in this trial is indeed the re-implanted chondroprogenitor residing on the superficial surface of the harvested cartilage tissue. By identifying the reparative cell in this application, a less invasive methodology for reparative cell isolation could be developed, thereby greatly reducing donor site morbidity as well as enhancing the efficacy of the therapy.

TissueGene Inc is currently investigating the safety of intra-articular application of chondrocytes modified virally to over express TGF- β 1 as a potential treatment for arthritic lesions [53]. Although preliminary results are not yet available, re-creation of the embryonic environment by supplementing cells with TGF- β 1 may significantly contribute to cartilage repair over the application of chondrocytes alone especially after their *in vitro* expansion and consequential de-differentiation.

The benefits and disadvantages of allogeneic versus autologous cell-based clinical therapies continue to be debated. In a clinical study supported by the National Institutes of Health, this specific question will be addressed by comparing autologous and allogeneic MSC therapies in the setting of heart failure [54]. Recent Phase I clinical administration of allogeneic MSC therapies to myocardial infarct (MI) patients validated the safety of allogeneic cells [54] and autologous cells [55]. However, their long-term survival, engraftment and mechanism of action remains unclear [56].

Conclusions

Several million people world wide suffer from OA, a chronic, debilitating disorder of the articulating joints. As current clinical interventions do not stimulate the generation of a mechanically sound reparative tissue, but focus on the short-term relief of OA symptoms, the field now looks to progenitor cell-based therapies as our future; specifically progenitor cells primed for chondrogenic differentiation. Chondroprogenitors residing in the adult have hypothetically been primed for chondrogenic differentiation with Wnts, FGFs and TGF- β superfamily members; just as embryonic limb mesenchyme is influenced, and, when stimulated, will differentiate into high quality articular cartilage.

Recent chondrocyte- or MSC-based clinical trials have failed to meet their primary endpoints, often due to our minimal knowledge of their mechanism of action and fate following systemic infusion. Nevertheless, the clinical application of chondroprogenitors for cartilage regeneration may have a bright future with a greater understanding of their embryonic development and the identification of a reliable tissue source. The clinical application of a homologous chondroprogenitor population will eliminate the need for heterogeneous cell therapies [56] and result in an efficacious, minimally invasive approach to articular cartilage repair.

Figure Legends

Figure 1. Potential sources for isolation of chondroprogenitors. Progenitor cells with chondrogenic potential have been isolated from bone marrow, synovium, perichondrium and cartilage itself. The relative ability of these cells to contribute to normal cartilage homeostasis or repair of diseased tissue may be related to their niche or developmental origin.

Table 1. Overview of progenitor cell tissue sources. Depending upon the adult source tissue, isolated progenitor cells vary in cell surface phenotype, expansion and differentiation potential. Before clinical application, careful consideration of the adult tissue source and capability of the derived reparative cell is therefore warranted.

Source	Advantages	Disadvantages	Cell Surface Phenotype
Bone Marrow [33] [44] [31-32]	<ul style="list-style-type: none"> • Twenty to fifty percent of cells are tri-potent • Contains specifically chondroprogenitor sub-populations • High expansion potential 	<ul style="list-style-type: none"> • Heterogeneous population of cells • Contains fewer CFU-Fs as compared to other cell sources • Invasive procedure to harvest 	CD105 ⁺ , CD73 ⁺ , CD44 ⁺ , CD90 ⁺ , CD271 ⁺ , CD14 ⁺ , CD13 ⁺ , CD166 ⁺ , CD34 ⁺ , CD45 ⁻ , CD117 ⁻ , CD31 ⁻ , VEGFR-2 ⁻
Synovium and Synovial Fluid [44] [38]	<ul style="list-style-type: none"> • High expansion potential regardless of donor age • Superior chondrogenic differentiation potential • No reduction in cell number or potential with donor age • Increase in progenitor cell numbers in early OA 	<ul style="list-style-type: none"> • Heterogeneous population of cells 	CD105 ⁺ , CD73 ⁺ , CD44 ⁺ , CD90 ⁺ , CD271 ⁺ , CD13 ⁺ , CD166 ⁺ , CD10 ⁺ , CD34 ⁺ , CD45 ⁻ , CD117 ⁻ , CD31 ⁻ , VEGFR-2 ⁻
Infrapatellar Fat Pad [40] [44]	<ul style="list-style-type: none"> • Abundant source of progenitor cells • Superior retention of differentiation potential upon expansion 	<ul style="list-style-type: none"> • Comparable differentiation capacity to other tissue sources • Relatively early senescence 	CD105 ⁺ , CD73 ⁺ , CD44 ⁺ , CD166 ⁺ , CD271 ⁺ , CD13 ⁺ , CD90 ⁺ , CD34 ⁺ , CD45 ⁻ , CD31 ⁻ , VEGF-2 ⁻
Tendon [43]	<ul style="list-style-type: none"> • Tri-potent cell population, positive chondrogenic differentiation, however, excelling in osteo- and adipogenic potential • Significant expansion potential 	<ul style="list-style-type: none"> • Low availability of autologous tendon tissue • Minimal chondrogenic capacity 	CD105 ⁺ , CD73 ⁺ , CD44 ⁺ , CD90 ⁺ , CD271 ⁺ , CD13 ⁺ , CD166 ⁺ , CD14 ⁺ , CD34 ⁺ , CD45 ⁻ , CD117 ⁻ , CD31 ⁻ , VEGFR-2 ⁻
Periosteum[28]	<ul style="list-style-type: none"> • Progenitors are multi-potent • Significant <i>in vitro</i> expansion potential and clonogenicity despite donor age 	<ul style="list-style-type: none"> • Consists of a heterogeneous population of cells <ul style="list-style-type: none"> • Invasive harvest procedure 	CD105 ⁺ , CD166 ⁺ , CD13 ⁺ , CD73 ⁺ , D7-FIB ⁺ , CD90 ⁺ , CD44 ⁺ , CD10 ⁺ , CD34 ⁺ , CD45 ⁻ , CD117 ⁻ , CD31 ⁻ , VEGFR-2 ⁻
