Abstract—This paper presents a novel method for ultrasonic range estimation. The method uses a wideband Frequency Hop Spread Spectrum (FHSS) ultrasonic signal to increase robustness to noise and reverberation. The method applies cross-correlation with earliest peak search and a novel minimum variance search technique to correct the error in the cross-correlation Time of Flight estimate to within one wavelength of the carrier before applying a phase shift technique for sub-wavelength range refinement. The method can be implemented digitally in software and only requires low cost hardware for signal transmission and acquisition. Experimental results show an accuracy of better than 0.5 mm in a typical office environment.

Index Terms—ultrasonic, FHSS, range estimation, cross-correlation, phase shift.

I. INTRODUCTION

RANGE measurement is important for many applications, including navigation tools for humans and robots, building mapping, interactive games, resource discovery, asset tracking and location-aware sensor networking [1-8]. Many range measurement techniques have been introduced in the literature, making use of various technologies such as lasers, infrared, radio frequency and ultrasonic signals [8-11]. Of these techniques, ultrasonic signals are distinguished by their capability to estimate range with a high degree of resolution at low cost. Their accuracy is primarily due to the low velocity of ultrasonic wave propagation in air, allowing high accuracy when estimating the signal's propagation distance based on a Time of Flight measurement. Errors can occur due to random medium displacements and change in the speed of sound with humidity and temperature changes in the medium. However these errors are typically small in indoor environments. [8,30].

Many ultrasonic range measurement methods have been proposed in the literature [12-19]. Time of Flight (TOF) and phase shift methods are used in most ultrasonic range measurement systems. The TOF method depends on measuring the time taken by an ultrasonic signal to travel between a transmitter and a receiver. The distance between the transmitter and the receiver is then calculated by multiplying the estimated Time of Flight by the acoustic propagation velocity. The delay

of the peak of the cross-correlation between the transmitted and the received signals can be used to estimate the TOF relative to a Radio Frequency synchronization signal. Alternatively the phase shift method is sometimes used to estimate the distance between the transmitter and the receiver by measuring the phase difference between the transmitted and the received signal. The phase shift method is typically more accurate than the cross-correlation based TOF method. However, with the phase shift method, the maximum range that can be estimated is limited to one wavelength of the transmitted signal [15, 17].

This paper proposes a novel method for ultrasonic range estimation. The method uses a wideband Frequency Hop Spread Spectrum (FHSS) ultrasonic signal for robustness to typical signalling impairments, i.e. noise, multi-path and interference from other sources. The method applies cross-correlation TOF estimation with earliest peak search. A novel minimum variance search technique is used to correct the errors in the cross-correlation TOF estimate to within one wavelength of the carrier before adding the phase shift for sub-wavelength range refinement. The accuracy of the method is assessed in simulation and by experiment. The accuracy of the method is shown to exceed that of previously proposed methods. In addition, the method does not require the use of custom measurement circuitry and can be implemented digitally in software.

The rest of this paper is structured as follows: Section 2 discusses related work. Section 3 explains the proposed method. Section 4 details the experimental method. Simulation results and experimental results are provided in Section 5. Section 6 concludes the paper.

II. RELATED WORK

The single-frequency continuous wave phase shift method [12] is the basic technique used to estimate range using ultrasonic signal with high accuracy. However the maximum range that can be estimated using this technique alone is limited to one wavelength of the carrier frequency which means that at 40 KHz the maximum range is limited to 8.575 mm assuming a sound velocity of 343 m/s. Multi-frequency continuous wave phase shifts [13], [14] was used to increase range by using the difference in phase between frequencies ($\Delta\theta$) and the difference in frequencies (ΔF). However the maximum range is still limited to $(C/\Delta F)$ where C is the sound velocity.

M. M.Saad, and C. J.Bleakley are with the School of Computer Science & Informatics, University College Dublin, Belfield, Dublin 4, Ireland, e-mail: {mohamed.saad, chris.bleakley}@ucd.ie. Simon Dobson is Professor of Computer Science in the School of Computer Science at the University of St Andrews UK, e-mail: sd@cs.st-andrews.ac.uk

In [15], Hong Hua applied the phase shift method to the envelope of an Amplitude Modulated signal. A low frequency ultrasonic signal modulated by a high frequency signal with proper AM index factor is generated. The basic phase shift method is applied to the received envelope of the AM modulated signal. This extends the range of the system to the wavelength of the lowest frequency used. In Hong Hua's system the lowest frequency which could be artificially generated was 100 Hz giving a maximum range of around 3.43 m.

Frequency change detection and phase shift using a Binary Frequency Shift-Keyed signal was proposed in [16]. This technique uses a frequency change detector to estimate the Time of Flight and refine the estimate by adding the phase shift measured by a digital phase meter. Amplitude change and phase inversion detection and phase shift using Amplitude Modulation and Phase Modulation Envelope Square Wave form (APESW) was proposed in [17], [18], [19]. This technique is quite similar to that proposed in [16] except that an amplitude and phase change detector is used for Time of Flight estimation instead of a frequency change detector. The accuracy of these two methods is significantly reduced by the presence of noise. They also need custom analog circuitry with sharp timing synchronization between the transmitter and the receiver.

Of previously proposed Digital Signal Processing techniques for TOF estimation, detecting the peak of the cross-correlation between the transmitted and received signals is, in general, more accurate than other techniques such as threshold-detection, curve fitting, and sliding-window [20], [21], [22]. However the best resolution that can be achieved using cross-correlation is half the sampling period meaning that to obtain higher resolution, a higher sampling frequency must be used. Applying interpolation after the cross correlation was introduced as a solution to achieving subsample accuracy [23], [24], [25]. A combined cross-correlation and phase shift method was proposed in [26], [27] where the cross-correlation is used for a first estimate of the Time of Flight (TOF) and a phase shift method is applied to refine the final result to gain better accuracy. This method gives good results when the accuracy of the cross-correlation stage is within one wavelength of the ultrasonic carrier but if the output of the cross-correlation stage is in error by more than one wavelength of the carrier then the phase shift refining stage can't correct this error and it appears in the final estimate as a significant range error.

Almost all ultrasonic range measurement systems previously proposed in the literature use narrowband ultrasonic signals and they have been tested in ideal reverberation-free environments. Narrowband systems are not robust to in-band noise and are highly affected by multi-path caused by reflections from walls and surrounding obstacles [28,29]. Hazas and Ward [29] proposed the use of wideband ultrasonic signalling with Direct Sequence Spread Spectrum (DSSS) modulation to improve performance under conditions of noise and reverberations. In [28] Frequency-Hopped Spread Spectrum (FHSS) modulation has shown to provide robustness to multipath and noise and has found to outperform both DSSS and impulsive signalling.

Fig. 1: Frequency Hop Spread Spectrum.

This paper proposes a novel method for ultrasonic range estimation. The method uses a wideband Frequency Hop Spread Spectrum (FHSS) modulation and applies cross-correlation with earliest peak search and a novel minimum variance search technique to correct errors in the cross-correlation TOF estimate to within one wavelength of the carrier before adding the phase shift for sub-wavelength range refinement. Compared to previous work on ranging accuracy the proposed method has the following novel features:

- Wideband ultrasonic signal with FHSS modulation to enhance robustness to multipath and noise.
- Simple cross-correlation with earliest peak search technique to extract the direct path from multipaths.
- A minimum variance search technique to correct the error in the cross-correlation TOF estimate to within one wavelength of the carrier.
- Easy digital implementation without the need for complex custom analog circuitry.

III. PROPOSED METHOD

The proposed method uses Frequency Hop Spread Spectrum FHSS modulation and a novel algorithm for range estimation. The follow subsections explain these two points in more detail.

A. Frequency Hop Spread Spectrum FHSS

In Frequency-Hopped Spread Spectrum (FHSS) modulation a carrier hops between a set of frequencies within the available bandwidth. Figure 1 shows how the carrier hops between different frequencies with time. A pseudorandom sequence determines the frequency hopping pattern ensuring orthogonality and collision avoidance between signals. The equation that describes the FHSS carrier signal is as follows:

$$X^{(k)}(t) = \sin(2\pi f^{(k)}t + \phi) \quad (1)$$

where (k) denotes user k , and $f^{(k)}$ is the carrier frequency which is a function of time and the pseudorandom sequence of user k .

Figure 2 shows the spectrogram of the FHSS signal used in this work.

Fig. 2: Spectrogram of the FHSS signal.

B. Range Estimation Algorithm

Consider an ultrasonic transmitter sending a FHSS signal. The signal is received by a wideband ultrasonic receiver separated by a distance L from the transmitter. The transmitter and the receiver are synchronized meaning that the receiver is aware of the signal transmission time. Signal acquisition is performed digitally using an Analog to Digital Converter (ADC) with a sampling frequency F_s . The proposed method uses three procedures to estimate the distance between the transmitter and the receiver:

- Cross-correlation
- Earliest peak search.
- Phase shift calculation.
- Minimum variance search.

1) *Cross-correlation* : A coarse estimate of the signal TOF between the transmitter and the receiver can be obtained by finding the delay of the earliest peak of the cross-correlation of the received signal with the reference transmitted signal [31]. The TOF is the delay associated with the peak in samples (n_{cross}) multiplied by the sample period ($1/F_s$). The estimated distance between the transmitter and the receiver can be calculated as:

$$L_{cross} = n_{cross}C/F_s \quad (2)$$

where C is the propagation speed of sound on air and F_s is the sampling frequency used for signal acquisition.

Figure 3 shows a typical cross-correlation plot where the peak associated with the time delay between the transmitter and the receiver can be clearly seen.

The maximum range that can be estimated using cross-correlation extends as far as the received signal has reasonable signal to noise ratio. The finest time resolution that can be obtained using cross-correlation is limited to $0.5/F_s$. For better resolution, higher sampling rates are required. In addition, the cross-correlation peak can be in error by one or more samples due to noise.

2) *Earliest peak search* : The peak associated with the correct delay is not always the highest peak. In some cases, the

Fig. 3: Cross-correlation between the transmitted and the received signal.

direct path can experience attenuation giving it a lower cross-correlation peak than other indirect multipaths. In other cases, a number of indirect paths can combine to produce a peak greater than the one associated with the direct path. Herein, a search mechanism is applied to find the earliest arriving cross-correlation peak above the noise floor [30]. The earliest peak is assumed to belong to the direct path that gives the correct TOF. The highest cross-correlation peak is first found and then a search back mechanism is applied to search for the earliest peak with amplitude greater than 0.7 of the highest peak. The ratio 0.7 was determined experimentally. It was found to be sufficiently high so that the peaks are above the noise floor even at low signal to noise ratios and sufficiently low to guarantee detection of the direct path peak even with high reflection coefficients.

3) *Phase shift calculation* : From the previous cross-correlation stage an estimate for the distance L_{cross} is obtained. The phase shift is used to refine this distance estimate. An error ΔL between the estimated distance L_{cross} and the true distance L is assumed. This error can be written as:

$$\Delta L = L - L_{cross} \quad (3)$$

The phase shift method is used to estimate ΔL with high accuracy and refine the final estimate of the distance L .

Consider that the received signal is:

$$y(t) = s(t - L/C) + n(t) \quad (4)$$

and the reference signal delayed according to L_{cross} is:

$$x(t) = s(t - L_{cross}/C) \quad (5)$$

where $s(t)$ is the transmitted signal, $n(t)$ is random noise, and C is the sound propagation velocity. The phase shift between $y(t)$ and $x(t)$ gives an estimate of ΔL . This estimated $\hat{\Delta L}$ is then used to refine the final range estimate as follows:

$$\hat{L} = L_{cross} + \hat{\Delta L} \quad (6)$$

Since the FHSS signal's carrier frequency varies with time, a

phase shift is calculated for each hop. A cross spectral density method is used to calculate the phase shift of the received signal $y(t)$ related to $x(t)$ which is the reference transmitted signal delayed according to L_{cross} . The following equations explain calculations of phase shift for each individual hop [34,35]:

$$G_{x_m y_m}(\omega) = X_m(\omega) Y_m^*(\omega) \quad (7)$$

where $G_{x_m y_m}$ is the cross spectral density, ω is the radian frequency which is assumed to be discrete, $X_m(\omega)$ and $Y_m(\omega)$ are the Discrete Fourier Transforms of the m^{th} hop of $x(t)$ and $y(t)$ respectively, and $*$ denotes the complex conjugate operation.

$G_{xy}(\omega)$ can be related to the transmitted signal $s(t)$ by:

$$G_{xy}(\omega) = G_{ss}(\omega) e^{j(\omega\tau + \epsilon)} \quad (8)$$

where $G_{ss}(\omega)$ is an estimate of the real cross spectral density of the transmitted signal $s(t)$, τ is the time delay between the two signals $x(t)$ and $y(t)$, and ϵ is the error in phase due to noise and the finite data record.

The estimated phase shift associated with carrier frequency ω_m can be written as:

$$\hat{\phi}_m = \text{ang}(G_{x_m y_m}(\omega_m)) = \omega_m \tau + \epsilon_m \quad (9)$$

The standard deviation of the phase estimate is approximated by:

$$\sigma[\hat{\phi}_m] \approx \left[\frac{1 - C_{xy}(\omega_m)}{2C_{xy}(\omega_m)} \right]^{1/2} \quad (10)$$

where C_{xy} is the coherence function between $x(t)$ and $y(t)$ defined by :

$$C_{xy}(\omega_m) = \frac{|G_{xy}(\omega_m)|^2}{G_{xx}(\omega_m) G_{yy}(\omega_m)} \quad (11)$$

From $\hat{\phi}_m$ and the sound propagation velocity C an estimated refinement distance associated with the m^{th} hop $\hat{\Delta}L_m$ can be written as:

$$\hat{\Delta}L_m = \frac{\hat{\phi}_m}{\omega_m} * C \quad (12)$$

Since the value of $\hat{\phi}_m$ is limited to $\pm\pi$ the maximum refinement range that can be achieved by the phase shift without ambiguity is limited to $\pm C/2F_c$, i.e. *half the wavelength of the carrier frequency*.

After calculating $\hat{\Delta}L_m$ for all the hops $\hat{\Delta}L$ can be obtained by averaging $\hat{\Delta}L_m$ over all the hops:

$$\hat{\Delta}L = \frac{\sum_{m=0}^{M-1} \hat{\Delta}L_m}{M} \quad (13)$$

where M is the number of hops in the signal.

4) *Minimum variance analysis* : Clearly the phase shift method fails when the error in the cross-correlation range estimate is greater than the maximum refinement range which can be achieved by the phase shift; i.e.:

$$|L - L_{cross}| > \lambda/2$$

where λ is the shortest carrier wavelength.

In some cases L_{cross} is in error by more than $\lambda/2$ especially in low signal to noise and/or high reverberation scenarios.

Hence we propose to use the variance V of the phase shift refinement range estimated from different hops as an indicator of the quality of the estimated range L_{cross} .

$$V = \sum_{m=0}^{M-1} \frac{(\hat{\Delta}L - \hat{\Delta}L_m)^2}{M} \quad (14)$$

In general, V is low when ΔL is less than $\lambda/2$ as $\hat{\Delta}L_m$ estimated over different hops provides consistent estimates of ΔL . When ΔL is greater than $\lambda/2$, V is large due to variations in $\hat{\Delta}L_m$ estimated at different hops. Hence the value of V can be used to check whether ΔL is smaller than $\lambda/2$.

An iterative procedure is used to search across a number of candidate range estimates, for each candidate, the phase shifts refinements $\hat{\Delta}L_m$ are obtained and used to determine $\hat{\Delta}L$ and V . The candidate range with minimum V is selected as the correct range estimate. The candidate ranges are integer samples delays in a window of length $(L_w + 1)$ centred on the delay associated with the cross-correlation peak.

$$L_{cross} - L_w/2 : L_{cross} + L_w/2$$

Figure 4 shows the values of V for a window of 400 samples length. The minimum value of V which is associated with the correct range candidate is clearly observed. Figure 5 shows the values of V for the same window in the case of low signal to noise ratio (SNR = -10 dB). Despite the noise, the candidate with the minimum variance is still clear.

5) *Summary* : The following pseudo code explains the overall range estimation algorithm:

R_{xy} : Cross-correlate the received signal with the transmitted reference signal.

L_{cross} : Find the range candidate associated with earliest arriving cross-correlation peak.

L_w : Define the candidates window length.

for $l = L_{cross} - L_w/2 : L_{cross} + L_w/2$ **do**

for $m = 0$ to $M - 1$ **do**

 Calculate $\hat{\Delta}L_m$.

end for

 Calculate V_l .

 Calculate $\hat{\Delta}L$.

end for

$l_{correct}$: Find the range candidate associated with the minimum value of V .

$\hat{L}$: Calculate the final refined range estimate.

IV. EXPERIMENTAL METHOD

The range estimation algorithm was implemented in software using *MATLAB* and simulated prior to experiments. The image method [32] was used to obtain synthetic impulse responses for a 4x4x4 m room with reflection coefficients for walls, ceiling and floor equal to 0.6 and a Signal to Noise Ratio (SNR) equal to 20 dB unless otherwise stated. A FHSS signal was designed with 16 frequency slots in the band between 28-36 kHz with 460 Hz separation between adjacent frequencies. The signal consists of 16 hops; each hop occupies a time slot of 2.2 millisecond.

Fig. 4: Values of phase shift variance V for 400 range candidates at high SNR (20 dB).

Fig. 5: Values of phase shift variance V for 400 range candidates at low SNR (-10 dB).

Actual experiments were performed using the same signal applied in a prototype range measurement system. The transmitters used were Prowave 250ST180 piezoelectric transducers [33] which have a bandwidth of 2 kHz, centred at 41 kHz. A bandwidth expansion circuit giving a useable bandwidth of 30 kHz was used to support wideband modulation [34]. SPM0204 ultrasonic sensors were used as receivers [35]. These microphones, based on CMUT technology, have nearly a flat response between 10 and 70 kHz. A Digital Signal Processing (DSP) board from Sundance, model 361A was used for signal acquisition [36]. It includes a C6416 DSP from Texas Instruments with two daughter boards, a SMT377 with 8 independent Digital to Analog Converters (DACs) and a SMT317 with an 8-channel Analog to Digital Converter (ADC). Coaxial cables were used to connect the daughter

(a) Office room

(b) Transmitter

(c) Receivers

Fig. 6: Pictures of experimental setup.

cards to the transmitter and receiver boards. The sampling frequency used was 117.5 kHz which is the lowest sampling frequency greater than $2F_c$ provided by the DSP board hardware. F_c is assumed to be equivalent to the highest carrier frequency among the FHSS frequency slots. The carrier frequencies are determined by the bandwidth of the ultrasonic transducer and the FHSS signal design. The value of F_c in these experiments was 36 kHz. The experimental system was installed in a typical office room with dimensions 350x285x270 cm. The sound velocity was assumed to be constant during the experiments. The variation in temperature and humidity effects on sound velocity was assumed to be negligible as the measurement were taken over a short period of time. Figure 6 shows pictures of the experimental system setup.

V. RESULTS

In order to evaluate the performance of the proposed method simulation and experimental results were obtained.

A. Simulation results

An ultrasonic transmitter sending the FHSS signal described in Section 3 was located at the corner of the room. The receiver is moved between 400 different locations in the room and in each location the received signal was processed and the range to the transmitter was estimated using the proposed algorithm. The simulation was run 100 times for each location and an estimate was obtained for each simulation run giving a total of 40,000 estimates.

Without earliest peak search	9%	11%	13%	18%	21%	23%	30%
With earliest peak search	9%	8%	9%	11%	11%	10%	14%
Improvement	0%	3%	4%	7%	10%	13%	16%

Table I shows that the proposed earliest peak search technique improves the range estimates for various Signal to Noise Ratios. It compares the percentage of errors greater than $\lambda/2$ when estimating the range using cross-correlation only and cross-correlation with earliest peak search.

Table II shows that the proposed earliest peak search technique improves the range estimates for various reflection coefficients. It compares the percentage of errors greater than $\lambda/2$ when estimating the range using cross-correlation only and cross-correlation with earliest peak search.

Table III shows that the proposed minimum variance search technique improves the range estimates for various Signal to Noise Ratios. It compares the percentage of errors greater than 0.5 mm when estimating the range using cross-correlation with earliest peak and phase shift without minimum variance search, and cross-correlation with earliest peak and phase shift with minimum variance search.

Table IV shows that the proposed minimum variance search technique improves the range estimates for various reflection coefficients. It compares the percentage of errors greater than 0.5 mm when estimating the range using cross-correlation with earliest peak and phase shift Without minimum variance search, and cross-correlation with earliest peak and phase shift with minimum variance search.

Figure 6 shows the cumulative error of the estimated ranges using cross-correlation only and cross-correlation with earliest peak search for all 40,000 estimates when SNR=0 dB and reflection coefficient =0.7. Figure 7 shows the cumulative error of the estimated ranges using cross-correlation with earliest peak and phase shift, and when using cross-correlation with earliest peak and phase shift with minimum variance search for

TABLE III: Percentage of errors greater than 0.5 mm using the proposed method with and without minimum variance search (reflection coefficient = 0.7).

Fig. 7: Cumulative error of the estimated range using cross-correlation with and without earliest peak search.

all 40,000 estimates when SNR=0 and reflection coefficients =0.7. Comparing Figures 6 and 7 the improvement due to incorporation of phase shift can be seen (note different x-axes). Simulations show the proposed system provides an accuracy of 0.2 mm in 90 % of cases. These results show the improved accuracy of the proposed method and illustrate its robustness to noise and multipath.

Controlled experiments were carried out to evaluate the performance of the proposed method and to compare it with other methods. Table V compares the Standard Deviation (σ) and the Root Mean Squared Error (RMSE) obtained using the proposed method (PM) with that obtained using cross-correlation with interpolation (including earliest peak search) (CC-INT), and cross-correlation alone (including earliest peak search) (CC). Signal to Noise Ratio (SNR) has been varied between -10 dB and 10 dB while the reflection coefficient was fixed to 0.7. 1000 simulation runs were performed for each SNR value. Results show that the proposed method (PM) outperforms other methods over a range of SNR values. Also it shows that the accuracy of the proposed method is very good at high SNR.

The accuracy of the proposed method was tested in the presence of other interfering sources using the same FHSS scheme. In simulation up to six transmitters sending different FHSS patterns were placed equidistant from the receiver in a 4x4x4 m room with reflection coefficients for walls, ceiling and floor equal to 0.65 and a Signal to Noise Ratio (SNR) equal to 20 dB. The number of simultaneously active

transmitters was varied from 1 to 6 and 1000 simulation runs were performed for each case. Table VI shows the values of the Standard Deviation (σ) and the Root Mean Squared Error (RMSE) obtained versus the number of active transmitters (NT). Results show that the proposed method is robust to interfering sources. Accuracy degrades some what when the number of transmitters increases but even so the overall accuracy is good.

The accuracy of the proposed method was tested over various distances. The signal to noise ratio was 20 dB at 0.5 m distance from the transmitter. Table VII shows the values of the Standard Deviation (σ) and the Root Mean Squared Error (RMSE) obtained from 1000 runs versus the distances between the transmitter and the receiver (from 0.5 m to 7m). Results show that the proposed method has a reasonable accuracy over a large range of source receiver separation. Accuracy decreases slightly as separation increases. This is due to signal attenuation with distance which causes degradation in the signal to noise ratio.

B. Experimental Results

Three receiver sensors were fixed on a Printed Circuit Board and the distance between them was measured with high accuracy. A transmitter was moved between three different locations while the receiver's board remained stationary. The ranges between the transmitter and the receivers' board were 2.1 m, 2.3 m, and 2.5 m for location 1, 2, and 3 respectively. A total of 125 range estimates from each individual sensor were obtained. Due to the lack of sophisticated tools to measure the true range between the transmitter and the receiver with sufficient accuracy, the differences between the estimated ranges to the three receivers were calculated by subtracting the estimated ranges for each pair of sensors. The estimated range differences were compared with the sensors physical separation measured with a micrometer allowing for angle of arrival. Figure 8 shows that the error is less than 0.5 mm in 90% of cases. The error is double simulation results due to subtraction of two estimates.

The receiver was separated by one meter from the transmitter and 100 estimates were obtained. The Standard Deviation of the estimates was 0.1619 mm. A second transmitter sending a different FHSS signal was located facing the receiver and separated by one meter from it. The Standard Deviation of the estimates when the two transmitters were sending simultaneously was 0.3140 mm. The same experiment was repeated with three transmitters and the Standard Deviation this time was 0.5392 mm. Table VIII summarizes the previous results. These results show that the proposed method is accurate and robust to other interfering sources.

VI. CONCLUSION

A novel method for range measurement using FHSS ultrasonic signals combining cross-correlation and phase shift methods was developed. The method picks the earliest peak in the cross-correlation of the received signal with the transmitted reference signal to obtain a first estimate of the range. A novel minimum variance search technique is applied to correct the error in the cross-correlation Time of Flight estimate to within one wavelength of the carrier before applying a phase shift for sub-wavelength range refinement. The simulation results show the robustness of the method to noise and multipath. The method was experimentally tested using low cost hardware and software in a typical office environment and it provides an accuracy greater than 0.5 mm in 90% of cases.

ACKNOWLEDGMENT

This work was conducted as part of the NEMBES project which was funded by the Higher Education Authority (HEA) of Ireland under the Programme for Research in Third Level Institutions, cycle 4 (PRTL14).
