A U-turn in the Asymmetric Appel Reaction: Stereospecific Reduction of Diastereomerically Enriched Alkoxyphosphonium Salts allows the Asymmetric Synthesis of $P$-Stereogenic Phosphines and Phosphine Boranes

Kamalraj V. Rajendran, Jaya S. Kudavalli, Katherine S. Dunne and Declan G. Gilheany*[a]

Keywords: Phosphine / Phosphine borane / $P$-stereogenic / $P$-chiral / $P$-chirogenic / Asymmetric synthesis / Appel conditions / Alkoxyphosphonium salts.

An efficient one pot synthesis has been developed of enantioenriched $P$-stereogenic phosphines and phosphine boranes from the corresponding racemic phosphines in excellent yield under asymmetric Appel conditions. The chiral auxiliary (menthol) can also be recovered unchanged. The simple and efficient protocol significantly expands the scope of our asymmetric Appel process.

The crucial step in the preparation involves stereospecific reduction of intermediate diastereomeric alkoxyphosphonium salts, which are obtained by reacting phosphine, hexachloroacetone, and menthol. Thereby, reaction with LiAlH$_4$ or NaBH$_4$ gives the corresponding phosphines or phosphine boranes respectively.

Introduction

Asymmetric catalysis has become an essential strategy for carrying out various asymmetric transformations[1] and enantioenriched phosphate ligands are common catalyst components.[1a-c] Thus significant effort has been expended in the design, synthesis, and testing of new enantiomerically pure phosphines for various synthetic purposes.[2] An important part of that effort has seen the development of a large number of methodologies for the synthesis of $P$-stereogenic phosphines[3] and a large number of such enantiomerically pure phosphate ligands have been reported in the literature.[1c,4,5] Some of these methods are very effective, but each of them has its own limitations and it is true to say that a general procedure for the synthesis of $P$-stereogenic phosphines has not been developed thus far. In seeking a general solution to this problem, we developed[6] a dynamic kinetic resolution (DKR) in the oxidation of phosphines under Appel[7] reaction conditions (Scheme 1). The purpose of this communication is to disclose a significant improvement to this methodology that allows the expansion of the range of compounds synthesised to include enantiorenriched tertiary $P$-stereogenic phosphines or their protected phosphate boranes.

Results and Discussion

Our asymmetric Appel methodology (Scheme 1) utilises hexachloroacetone (HCA) as a chlorine source and a chiral alcohol such as menthol to make enantioenriched phosphate oxides from racemic phosphines. Although this is an efficient way to make $P$-stereogenic phosphorus compounds, it suffers from some drawbacks, one of which is that a subsequent (and potentially problematic) stereospecific reduction of the product phosphate oxide[4d,8] is required to obtain the target phosphate. Another drawback is that the menthol auxiliary is converted to the derived chloride making its reuse difficult.

As part of our studies of this process with various alcohol/phosphine combinations, we observed, in the $^{31}$P-NMR, an unequal pair of signals in the region $\delta$ 65-67 ppm. These were identified[6] as diastereomeric alkoxyphosphonium salts (DAPS), which undergo Arbuzov collapse to form the phosphate oxide (Scheme 2). Denton and co-workers have recently isolated and characterised similar alkoxyphosphonium salt intermediates in their catalytic Appel reactions.[9]
In order to isolate a stable form of these intermediates we used (R)-BINOL as the alcohol in an Appel type reaction with methyl(phenyl)-o-tolylphosphine at -78 °C in dry toluene. On addition of HCA, a mixture of diastereomeric arylphosphonium salts precipitated (Scheme 3; R*OH = (R)-BINOL). Because they are unable to undergo Arbuzov collapse, these could be isolated and characterised (as the mixture) by $^3$P-NMR, HRMS and elemental analysis (see supporting information for details). The salts were found to have been formed in a diastereomeric excess (de) of 46% (as measured by integration of their $^3$P signals at δ 74.7 and 76.6 ppm). The salts were then subjected to reduction using LiAlH$_4$, resulting in full conversion to enantioenriched methyl(phenyl)-o-tolylphosphine (Scheme 3). The enantiomeric excess of the phosphine was determined to be 46% (by CSP-HPLC analysis of the corresponding phosphine borane formed by treatment with BH$_3$·THF). This indicated that there had been no loss of stereochemical information during the reduction step. (R)-BINOL was also recovered.

We realised that this transformation might also be applied to the transient DAPS formed with menthol under Appel conditions, by application of the reducing agent before Arbuzov collapse to the phosphine borane using NaBH$_4$ according to Scheme 3.

Table 1 also gives, for comparison, the analogous enantioselectivities of the phosphine oxide products obtained in the regular asymmetric Appel reaction of the same phosphines, reported in our previous work.[6] It can be seen that, mostly, these are the same, the exceptions being where there are notable changes in the alcohol (entry 6) or phosphine used (entries 10-12). We attribute these variations to the need for optimisation of the conditions in these cases.

At the same time that this work was in progress, we had been studying this reaction conditions: phosphine (1.1 mmol), alcohol (1.32 mmol), HCA /-78 ° C, crude yields >95% (as determined by $^3$P NMR); [b] see Chart 1; [c] measured following conversion to the borane with borane-THF, determined by CSP HPLC, a negative ee denotes that the major enantiomer was eluted second; absolute configurations determined as described in the SI; [d] ee of the analogous phosphine oxide formed when the DAPS was allowed to undergo Arbuzov collapse, from references [6]; [e] isolated yields >85%; [f] configuration not assigned. We also studied this variant, Scheme 4, with various phosphine/alcohol combinations with the results shown in Table 2. In most cases the ees obtained are the same as those obtained in the LiAlH$_4$ reduction.
The significance of the results in Tables 1 and 2 does not lie in the absolute degree of selectivity obtained. We have focussed mostly on the use of inexpensive menthol as the chiral auxiliary to show proof of principle that the asymmetric Appel process can be on the use of inexpensive menthol as the chiral auxiliary to show proof of principle that the asymmetric Appel process can be. Also, the selectivities are, in proof of principle that the asymmetric Appel process can be. The solvent was removed under vacuum and column chromatography was used to recover intact in the molecular sieves for two minutes each and then flushed with N₂. This was repeated twice. The Young’s flask screw crown was removed under a good flow of N₂ and replaced with a rubber septum. While both vessels were under nitrogen the stock solutions were removed via syringe from the round-bottomed flasks and placed over the sieves in the Young’s flask and left overnight. For the HCA solution, molecular sieves (4 Å), which were flame-dried until red hot, were added to flame-dried Young’s flasks. The solvent was removed under vacuum with a heat gun focusing on the molecular sieves for 2 minutes each and then flushed with N₂. This was repeated twice. The screw cap of the Young’s flask was removed under a good flow of N₂ and replaced with rubber septa. Distilled HCA (1.1 mmol) was weighed into the Young’s flask and dry toluene was added to make up a solution of the required concentration (0.11 M) which was then left overnight. A similar procedure was followed to make up 0.11 M stock solutions of distilled phosphines in dry toluene.

The significance of the results in Tables 1 and 2 does not lie in the absolute degree of selectivity obtained. We have focussed mostly on the use of inexpensive menthol as the chiral auxiliary to show proof of principle that the asymmetric Appel process can be manipulated to produce scismatic phosphines or phosphine boranes in one pot from a racemic phosphine. Also, the selectivities are, in most cases, the same as previously seen in the regular asymmetric Appel process. Thus we have significantly expanded the utility of our asymmetric Appel process. With this methodology in hand, we have embarked on an intensive study aimed at raising the degree of stereoselectivity in our process. In that context, an important point is that the chiral auxiliary can now be recovered intact in the choice of chiral alcohols for our selectivity studies, knowing that they can be recovered at the end of the reaction.

Conclusions

In conclusion, we have achieved an unprecedented one-pot enantio-enrichment of racemic phosphines and we have demonstrated the one-pot conversion of racemic phosphines to enantioenriched phosphine boranes. Both methods rely on the interception of diastereomeric alkyloxyphosphonium salts formed by dynamic resolution of racemic phosphines under asymmetric Appel reaction conditions. Further investigations into the scope of this reaction are underway.

Experimental Section

(A) Preparation and Pre-drying of Stock Solutions: Moisture was rigorously excluded in these experiments. Dry solvent used to make up stock solutions was obtained after processing through an Innovative Technology Inc. Pure Solv-400-3-MD solvent purification system (Grubb’s still). The water content of the solvent and stock solutions was determined by Karl Fischer titration to be less than 5 ppm. The alcohols, phosphines and hexachloroacetone (HCA) used were dried thoroughly before preparing the stock solutions as follows. The individual alcohols (1.32 mmol) were weighed into flame-dried and N₂-purged round-bottomed flasks and sufficient dry toluene (approx. 10 mL) added to dissolve the alcohol. The toluene was removed using a rotary evaporator to remove water via azeotrope. This process was repeated three times and then sufficient dry toluene was added to the alcohols under N₂ to make up solutions of the required concentration (0.132 M). Molecular sieves (4 Å), which were flame-dried until red hot, were added after cooling to flame-dried Young’s flasks. The toluene was removed under vacuum with a heat gun focusing on the molecular sieves for two minutes each and then flushed with N₂. This was repeated twice. The Young’s flask screw crown was removed under a good flow of N₂ and replaced with a rubber septum. While both vessels were under nitrogen the stock solutions were removed via syringe from the round-bottomed flasks and placed over the sieves in the Young’s flask and left overnight. For the HCA solution, molecular sieves (4 Å), which were flame-dried until red hot, were added to flame-dried Young’s flasks. The solvent was removed under vacuum with a heat gun focusing on the molecular sieves for 2 minutes each and then flushed with N₂. This was repeated twice. The screw cap of the Young’s flask was removed under a good flow of N₂ and replaced with rubber septa. Distilled HCA (1.1 mmol) was weighed into the Young’s flask and dry toluene was added to make up a solution of the required concentration (0.11 M) which was then left overnight. A similar procedure was followed to make up 0.11 M stock solutions of distilled phosphines in dry toluene.

(B) Optimised Procedure for LiAlH₄ Reduction with methylphenyl-o-tolylphosphine as example.

A solution of methyl(phenyl)-o-tolylphosphine (10.0 mL, 0.11 M 1.1 mmol) in anhydrous toluene was placed in a dry flask under N₂. In a separate flask were placed dry toluene solutions of HCA (10.0 mL, 0.11 M, 1.1 mmol) and (-)-menthol (10.0 mL, 0.132 M, 1.32 mmol) also under N₂. Both flasks were cooled to -78 °C and allowed to stir at this temperature for 10 minutes. After this time the phosphine solution was added slowly via cannula over 2 minutes. The temperature was maintained for 10 mins, at which point the formation of the diastereomeric salts was confirmed by ³¹P NMR (sampled as described in the SI) showing two peaks at δ 65.7 and 67.4 ppm. To the mixture was added LiAlH₄ solution (10.0 mL, 0.11 M in toluene, 1.1 mmol) dropwise at -78 °C. After the addition was complete the vessel was removed from the cooling bath and allowed to warm to room temperature. The reaction was stirred for a further 60 minutes, at which point the diastereomeric salts were shown to have been consumed and the phosphine formed (³¹P NMR signal at δ -36.2 ppm). BH₄⁻/THF complex (0.75 mL of a 2.0 M solution in THF, 1.5 mmol) was added. ³¹P NMR of the clear solution revealed one peak for the phosphine borane at δ 10.1 ppm. A portion of the reaction mixture was removed, concentrated under reduced pressure, diluted in HPLC mobile phase, filtered though a 0.2 µM Millipore Acrodisc and directly injected (10 µL) onto the HPLC system (see SI) for ee analysis. The remaining reaction mixture was diluted with EtOAc (15 mL) and water (10 mL). The organic layer was separated, and the aqueous layer was extracted with EtOAc (10 mL). The combined organic extracts were dried over MgSO₄ and concentrated under reduced pressure. The residue was passed through a column of basic alumina using degassed Et₂O. The solvent was removed under vacuum and column chromatography was carried out on silica gel (EtOAc, Rₚ 0.11) yielding the enantioenriched phosphine borane as a white solid (0.20 g, 96%, 79% ee (R)).

(C) Optimised Procedure for NaBH₄ Reduction with methylphenyl-o-tolylphosphine as example.

Experimental procedure as per section (B) up to the analysis of diastereomeric salts by ³¹P NMR. To the mixture was added NaBH₄ solution (11 mL of a 0.5 M solution in diglyme, 5.5 mmol) dropwise at -78 °C. After the addition was complete the vessel was removed from the cooling bath and allowed to warm to room temperature. The reaction was stirred for a further 60 minutes, at which point the diastereomeric salts were...
shown to have been consumed and the phosphine borane formed ($^3$P NMR signal at $\delta$ 10.1 ppm). Work up and analysis as per section (B) gave the enantioenriched phosphine borane as a white solid (0.19 g, 94%, 75% ee ($R$)).
