Urban Public Attitudes to the treatment of Psychological Problems and Depression in General Practice

Abstract:
A previous national study of public attitudes to depression indicated that only 17% spontaneously mentioned their general practitioner as someone who could help with depression, in contrast to 79% of respondents being willing to consult their G.P. in a similar U.K. survey. The present study undertook to examine the public perception of an urban sample to the treatment of depression in general practice and the factors associated with expressed unwillingness to consult. A random sample from the electoral register was drawn and 54 (89%) of 61 subjects selected were interviewed. While 85% of respondents were satisfied with their general practice care, only 24% to 52%, depending on the context and wording of the question, said that they would seek help from their general practitioner for depression. Factors associated with an expressed reluctance to consult were being male, dissatisfied with general practitioner care and believing that general practitioners were not qualified to treat depression. A previous national study of public attitudes to depression indicated that only 17% spontaneously mentioned their general practitioner as someone who could help with depression, in contrast to 79% of respondents being willing to consult their G.P. in a similar U.K. survey. The present study undertook to examine the public perception of an urban sample to the treatment of depression in general practice and the factors associated with expressed unwillingness to consult. A random sample from the electoral register was drawn and 54 (89%) of 61 subjects selected were interviewed. While 85% of respondents were satisfied with their general practice care, only 24% to 52%, depending on the context and wording of the question, said that they would seek help from their general practitioner for depression. Factors associated with an expressed reluctance to consult were being male, dissatisfied with general practitioner care and believing that general practitioners were not qualified to treat depression. When enquiring about depression, the respondents were not given a description or definition of depression, as it was defined in a previous study. While general practitioners have a central role to play in the treatment of psychological problems and depression, the results of both the Irish and UK studies suggest that this role is often not accurately perceived by the public. The aim of this study was to examine public perceptions of the role of the general practitioner with respect to depression. The present study undertaken to examine the public perception of an urban sample to the treatment of depression in general practice and the factors associated with expressed unwillingness to consult. A random sample from the electoral register was drawn and 54 (89%) of 61 subjects selected were interviewed. Factors associated with an expressed reluctance to consult were being male, dissatisfied with general practitioner care and believing that general practitioners were not qualified to treat depression.

Introduction
Few studies in Ireland have assessed patients satisfaction with their general practitioners and their views on the role of general practitioners in the treatment of psychological problems. In 1994/5, the Department of Health and Social Welfare's National Perceptions of General Practitioners survey ([1]) was used. However, a recent study in the United Kingdom also showed that general practitioners are not qualified to deal with personal problems. Respondents attitudes to consulting their general practitioners for depression were probed, both directly and indirectly, at different stages throughout the interview. In response to the question who could help with depression, only 30% of respondents suggested your general practitioner?, 52% of the sample replied, yes. However, in response to the more general question, Who could help with depression?, only 30% of respondents suggested a general practitioner and this included 6% who said they would consult their doctor specifically for referral to a mental health professional (Table).

Methods
A random sample of the public was drawn from the electoral register in the Dublin area and interviews were obtained in 54 (89%) of the 61 subjects selected who were contactable and suitable for interview. To ensure that the sample was representative, a probability-based method of stratifying the population of Dublin was chosen. Descriptors used to group the socio-economic characteristics of the population were age, class and sex. Using the classification of socio-economic groups contained within the electoral register, a ranking procedure was adopted. A random sample from the electoral register was drawn and 54 (89%) of 61 subjects selected were interviewed. The majority of respondents (85%) were either satisfied or very satisfied with the care they received from their general practitioner. However, more than half would not consult their general practitioner about personal difficulties or marital discord (32%), or for help with marital discord (32%). A previous national study of public attitudes to depression indicated that only 17% spontaneously mentioned their general practitioner as someone who could help with depression, in contrast to 79% of respondents being willing to consult their G.P. in a similar U.K. survey. The present study undertook to examine the public perception of an urban sample to the treatment of depression in general practice and the factors associated with expressed unwillingness to consult. A random sample from the electoral register was drawn and 54 (89%) of 61 subjects selected were interviewed. While 85% of respondents were satisfied with their general practice care, only 24% to 52%, depending on the context and wording of the question, said that they would seek help from their general practitioner for depression. Factors associated with an expressed reluctance to consult were being male, dissatisfied with general practitioner care and believing that general practitioners were not qualified to treat depression.

Results
Fifty-four people completed the interview giving a response rate of 89%. Four people were unsuitable for interview because of sensory or cognitive deficits. Fifty-two per cent of the sample were female and 48% were male. The 54 respondents ranged in age from 18 to 65 years and over. The breakdown for age was as follows: 18-27 (28%), 28-39 (20%), 40-51 (19%), 52-64 (15%) and over 65 (18%). Fifty-three per cent of respondents were married, 37% were single, 6% were widowed and 4% were separated or divorced. The distribution of the socio-economic groups was as follows: upper middle class (20%), lower middle class (20%), skilled working class (20%) and lower working class (26%). Statistical comparisons of demographic characteristics of the sample with those of the population from which it was drawn show they are not significantly different: gender (x2=7.36, P > 0.05), age (x2=7.36, P > 0.05), marital status (x2=3.91, P > 0.05), age (x2=5.04, P > 0.05) and socio-economic status (x2=6.41, P > 0.05).

When enquiring about depression, the respondents were not given a description or definition of depression, as it was defined in a previous study. While general practitioners have a central role to play in the treatment of psychological problems and depression, the results of both the Irish and UK studies suggest that this role is often not accurately perceived by the public. The aim of this study was to examine public perceptions of the role of the general practitioner with respect to depression. When enquiring about depression, the respondents were not given a description or definition of depression, as it was defined in a previous study. While general practitioners have a central role to play in the treatment of psychological problems and depression, the results of both the Irish and UK studies suggest that this role is often not accurately perceived by the public. The aim of this study was to examine public perceptions of the role of the general practitioner with respect to depression. The present study undertaken to examine the public perception of an urban sample to the treatment of depression in general practice and the factors associated with expressed unwillingness to consult. A random sample from the electoral register was drawn and 54 (89%) of 61 subjects selected were interviewed. While 85% of respondents were satisfied with their general practice care, only 24% to 52%, depending on the context and wording of the question, said that they would seek help from their general practitioner for depression. Factors associated with an expressed reluctance to consult were being male, dissatisfied with general practitioner care and believing that general practitioners were not qualified to treat depression.
When probing for their reasons for not consulting their general practitioner about depression, 22% of these respondents felt they were unable to deal with depression and could offer little help other than medication. Twenty per cent expressed a preference for consulting a mental health professional and a further 20% a desire to deal with the depression themselves.

Other factors were also associated with respondents' willingness to consult their general practitioner for depression. Respondents, R.P., who believed that the care they received from their doctor generally, were also significantly more likely to consult for depression (r=0.316, p<0.05). Similarly, respondents who were willing to consult their general practitioner about personal and marital problems were also significantly more likely to consult for depression (r=0.378, p<0.05).

In addition, males (76%) were significantly more likely than females (64%) to say they would not be prepared to consult their general practitioner about depression (x²=12.63, p<0.01) and males (62%) were also significantly more likely than females (38%) to look to family and friends as a source of help for depression (x²=4.07, p<0.05).

Discussion

Attitudes to the care provided by general practitioners in this study were generally positive, with the majority of respondents expressing satisfaction with the consultations with their doctor, a finding consistent with other Irish studies. However, the majority of respondents said they would not consult their general practitioner about a personal or marital difficulty, a finding that contrasts with British studies which have reported that people with mental health difficulties and personal, or emotional problems were more likely to approach their general practitioner for help than any other professional. This points to an apparent paradox, since the majority of the sample rated their general practitioner as excellent with respect to listening, communicating and allowing adequate time for the consultation. However, respondents reluctance to consult their general practitioner for such problems would appear to be at least partly due to their expressed belief that general practitioners are not adequately qualified to deal with such problems.

It might appear that respondents in the present study, when asked directly, showed some increase in willingness to consult their general practitioner about depression over the 1991 national survey, with 52% saying they would be prepared to consult their general practitioner about depression. However, it should be noted that when similarly framed questions to those of the 1991 survey were asked in this present study, only 24% of respondents spontaneously mentioned their general practitioner as someone who could help with depression, a figure more in keeping with the 17% expressed willingness to consult in the 1991 study. Both findings contrast with a recent British survey in which the majority of respondents (79%) said they would consult their general practitioner for depression. The reasons for the apparent differences in willingness to consult between the British and Irish studies is not clear. It may perhaps be a reflection of the greater availability of ancillary services in British general practice settings such as counselors, psychologists and practice nurses. There is also the consideration of the different practice mix of public and private patients. The fact that many people in the Republic of Ireland pay directly for their general practitioner services may also have contributed to some of the differences between the two studies. Consequently, such patients may be more likely to seek and have ready access to mental health professionals. This would appear to find some support in the finding that while 37% of the present sample favoured consulting a psychiatrist for depression, only 2% of respondents in the British study would consult a psychiatrist for depression and 1% said they would consult a psychologist. Some differences may also be attributable to the sample. As respondents in the present study were drawn entirely from an urban sample, they may perhaps have a greater awareness of, and accessibility to, a wide range of mental health professionals for the treatment of depression. The Irish national survey found that 25% of rural dwellers in contrast to 15% of urban dwellers expressed a willingness to consult their general practitioner for depression. While this urban-rural difference may be explained by the greater availability of mental health professionals in urban areas, it does not shed much light on the nature of the public of Ireland and the U.K., which would predict a much higher rate of mental health professional consultation in the U.K., where there is a greater percentage of the population resident in urban areas.

The results point to an association between other factors and respondents reluctance to consult their general practitioner. One factor examined was the effectiveness of seeking help from the local church or from one's religious beliefs. Although in the present study it is possible that this might be partly accounted for by their stronger preference for family and friends as a source of help for depression. Respondents who were satisfied with the care they received generally from their general practitioner were also more likely to consult for depression. However, since satisfaction with general practitioner care was high, clearly this is only a small part of the picture. Viewed by many respondents, the general practitioners are not adequately qualified to deal with depression, coupled with the belief that there was little they could do other than prescribe drugs and that they would be embarrassed to consult about their own problems.

To conclude, the results of this study suggest that there is an urgent need to increase public awareness of the role of the general practitioner in the management and treatment of psychological problems and to encourage people to seek help more readily from the primary care facilities.
