Abstract

Single forces are often observed in the source mechanism of volcanic seismicity. However, their underlying causative processes are still doubtful. The reliability of single force observations must be assessed, prior to analysing them in terms of physical mechanisms. Using numerical examples, we show that source mislocation and velocity mismodeling lead to strong spurious single forces. Layering in the velocity model produces converted S-waves and source mislocations modify the wavefield at the free surface (mainly through converted S- and surface waves). However, these waves can also be accurately reproduced in a homogeneous model by adding a vertical single force in the source mechanism, which mainly generates S-waves for large take-off angles. Hence approximate velocity models can lead to the appearance of strong single forces in source inversions. We conclude that, in moment tensor inversion, while single forces can be used in some cases to accommodate mismodeling errors, they cannot be reliably used to infer physical processes.

1. Introduction

Moment Tensor Inversion (MTI) is an extensively used tool to characterize the source mechanism of seismic events. When applied to volcanic seismicity, such as Long Period events (LP, with a main period of 1s here) (e.g. Kumagai et al., 2002; Lokmer et al., 2007; De Barros et al., 2011), Very Long Period events (VLP, with a main period of 20s here) (e.g. Ohminato et al., 1998; Chouet et al., 2003) and tremors (Davi et al., 2012), the resulting mechanisms usually exhibit a strong volumetric component (see Chouet and Matoza, 2013, and references therein). In earthquake seismology, MTI is usually limited to the reconstruction of the 6 components of the Moment Tensor (MT) of the equivalent point source, but in volcanic applications the 3 components of Single Forces (SF) are usually added (Ohminato et al., 1998). The recovered SFs often have strong amplitude (e.g. Ohminato et al., 2006; De Barros et al., 2011).

As shown by theoretical considerations (e.g., Takei and Kumazawa, 1994) or by laboratory experiments (e.g., James et al., 2004), SFs can be generated by mass transfer or by viscous fluid movement in the volcano. They are usually interpreted in terms of magma upwelling in conduits when observed in volcanic seismicity (Chouet et al., 2003; Ohminato et al., 2006). SFs have therefore been used to strongly constrain the source processes of the volcanic seismicity. However, as shown firstly by Ohminato et al. (1998) and Chouet et al. (2003), and later by Bean et al. (2008) and De Barros et al. (2011), uncertainties in both source location and velocity structure can lead to the

25 reconstruction of strong spurious SFs.

26

27 LP and VLP events are found to be shallow, in the first kilometer be-
28 low the surface (see e.g. Chouet et al., 2003; De Barros et al., 2009; Inza
29 et al., 2011). The upper part of the volcanic edifice is made of compliant and
30 weathered materials, leading to low and highly heterogeneous seismic veloc-
31 ities (e.g., Chouet et al., 1998; Mora et al., 2006; Cauchie and Saccorotti,
32 2013). However, the detailed velocity structure is usually poorly known,
33 hence homogeneous velocity models are commonly used when calculating
34 Green’s Functions (GFs) in MTI. This simplification is generally justified
35 by the use of long wavelengths (especially for VLP), which are similar to
36 the propagation distances. However, the lack of knowledge of the velocity
37 structure leads to uncertainties in source location (particularly for the depth
38 parameter) for joint location and MT inversion (Lokmer et al., 2007) or loca-
39 tion only (De Barros et al., 2009). It is now well documented that MTI can
40 suffer from a badly constrained velocity model (Jousset et al., 2004; Bean
41 et al., 2008; Kumagai et al., 2011), especially for the highest frequency (LP).
42 However, for both LP and VLP cases, it is not clear yet if SF should be
43 included or not in the inversion, and if they can be unequivocally interpreted
44 as physically present.

45

46 The aim of this paper is to numerically investigate why errors in the
47 velocity model and in the source locations generate apparent source related
48 SFs, and as a consequence, if it is meaningful to infer a physical process from
49 SFs. We will first show on synthetic data computed in models of Mt Etna (De

Barros et al., 2011) the effect on SFs of slight velocity modeling and sources location errors. We then simplify the problem in order to be able to identify the different waves responsible for the SF reconstruction, and generalize our findings to all frequency ranges.

2. Single forces in synthetic tests

Bean et al. (2008) showed that mismodeled complex media can have a detrimental effect on MT solutions for shallow volcanic sources. They suggest using stations as close as possible to the source. For this reason, a high-resolution experiment was undertaken on Mt Etna in 2008, including 30 stations within 2 km of the source area. De Barros et al. (2011) performed a MTI of the LP events recorded by this network. Here, using the same set-up, we compute synthetic data and GFs using the full wavefield elastic lattice algorithm of O'Brien and Bean (2004), including the topography of Mt Etna with a 40 m grid step. The GFs are calculated for a homogeneous model ($Vp_0=2000$ m/s, $Vs_0=Vp_0/\sqrt{3}$, $\rho=2300$ kg/m³), for a 400 m deep source. Synthetic data are computed for two cases: 1) velocity mismodeling case: a 200 m layer ($Vp=1600$ m/s) following real Mt Etna topography over a half-space with a 2400 m/s velocity; and 2) mislocation case: the homogeneous velocity model is used and the source location is misplaced by 120 m downward and by 90 m horizontally. The source has a 1 Hz Ricker wavelet time function and a vertical crack ($[3,1,1] \times 5 \cdot 10^{12}$ Nm) mechanism.

71

The MTI is performed in the frequency domain, with a fixed source location. In both cases (see fig. 1), and because of the exceptional number of

73

stations in the close proximity of the source, the source time function (STF)
 and the mechanism of the MT are quite well reconstructed, unlike the ampli-
 tudes. The amplitudes are in fact inversely proportional to the velocity (eq.
 4.29, Aki and Richards, 2002). A slight time shift exists between the STFs of
 the different MT components, but the decomposition leads to a near perfect
 [3,1,1] solution in both cases. The accuracy of the MT solution is ensured
 here by the exceptionally dense network (De Barros et al., 2011). However,
 strong SFs appear, with amplitudes reaching more than $5.5 \cdot 10^9$ N. SFs are
 mainly in the vertical direction for the velocity mismodeling case, and are
 inclined for the source mislocation case. Note that an amplitude of 10^9 N
 from the SF source and of 10^{12} Nm for a MT source lead to seismic waves
 of the same order of magnitude when the radiation pattern is neglected (see
 eq. 4.27 and 4.28 in Aki and Richards (2002)). Hence, even in such a simple
 case, both location and velocity mismodelings give rise to strong spurious
 SFs.

3. Origin of single forces

To understand the relationship between the mismodeling and the spurious
 SFs, we simplify the problem even further: we calculate synthetic waveforms
 generated by a purely isotropic source (1 Hz Ricker wavelet signature) in a
 medium without topography. In this way, the source generates only a P-wave,
 and all complex signatures can be attributed to the propagation effects. The
 different waves can be easily identified, allowing us to determine which waves
 are responsible for the spurious SF generation. The synthetic data are com-
 puted using the SKB code (Dietrich, 1988) based on the reflectivity method

98 of Kennett (1983), coupled with the wavenumber integration of Bouchon and
 99 Aki (1977).

100

101 Following the results from the previous section, we assume that the mech-
 102 anism and the STF of the MT components are properly recovered, but not
 103 the amplitude. We therefore constrain the inversion to a fixed mechanism
 104 (explosion) and STF (1 Hz Ricker wavelet), and invert for the amplitudes of
 105 the explosion and of the SFs required to accommodate the modeling uncer-
 106 tainties. Hence, by constraining the mechanism, we focus exclusively on the
 107 SFs reconstruction due to the modeling errors.

108 Synthetic data $\mathbf{U}_{Ex}^{True}$ are calculated from an explosion in two models
 109 (“true” models, see tab. 1): 1) a 2-layer model M_{True}^1 to investigate velocity
 110 mismodeling effects, and 2) a homogeneous model M_{True}^2 , with a shallow-
 111 source location, to investigate mislocation effects. We also calculate a set
 112 of signals in an homogeneous model (hereinafter referred as “approximate”
 113 model M_{app} , see tab. 1). This approximate model is equivalent to the model
 114 used in MTI in which Green’s functions are computed. Similarly to MTI of
 115 volcano data, this model is assumed to be the best model (usually homo-
 116 geneous) we have to represent the complex structure of the volcano. The
 117 signals are generated by an explosion ($\mathbf{U}_{Ex}^{app}$) and SFs ($\mathbf{U}_F^{app}$). In all models,
 118 the amplitude of the isotropic source is 10^{12} Nm, and the amplitude of the
 119 SFs in the M_{app} model is 10^9 N.

120

121 The data computed in the approximate model ($\mathbf{U}_{Ex}^{app}$ and $\mathbf{U}_F^{app}$) are used
 122 to reconstruct the synthetic signals ($\mathbf{U}_{Ex}^{True}$) computed in the “true” models,

such as:

$$\mathbf{U}_{Ex}^{True} = \alpha_{Ex} \mathbf{U}_{Ex}^{app} + \alpha_F \mathbf{U}_F^{app} \quad (1)$$

α_{Ex} and α_F are the amplitudes of the explosion and of the SFs in the “approximate” model, respectively, needed to fit the synthetic data (isotropic source in the M_{True} model). Since the sources have the same magnitude in the both true and approximate models, the amplitudes α_{Ex} and α_F can be seen as normalised amplitudes or magnitude correction factors. In order to reconstruct the synthetic data, these parameters are inverted to minimize the least square difference between the two sides of this equations. This inversion is performed in the frequency domain. Since the velocity models are different, time shifts might exist between the data, which are corrected by inverting for complex coefficients α_{Ex} and α_F . However, only the real part of these coefficients is later considered as the reconstructed imaginary part is negligible (more than 17 orders of magnitude smaller than the real part). In this inversion, either an explosion only (Ex), or an explosion and a vertical SF (Ex&Fz) or an explosion and two SFs (Ex&F) were considered. Hence, this is equivalent to a MTI where the MT part is constrained to an explosion with a known STF, and with or without SFs. We also define a misfit function in the least square sense as:

$$MIS = \frac{\sum_{t_i}^L [\mathbf{U}_{Ex}^{True}(t_i) - (\alpha_{Ex} \mathbf{U}_{Ex}^{app}(t_i) + \alpha_F \mathbf{U}_F^{app}(t_i))]^2}{\sum_{t_i}^L [\mathbf{U}_{Ex}^{True}(t_i)]^2} \quad (2)$$

3.1. Velocity mismodeling

The synthetic data are computed in the 2-layer model (M_{True}^1 , see table 1). To isolate the effects of the interface, the free surface is “switched off”,

144 leading to two joined half-spaces. The top layer ($V_{p1}=1600$ m/s) contains
 145 a line of receivers 200 m above the interface. The explosion, in the second
 146 layer ($V_{p2}=2400$ m/s), is located 200 m below the interface between the two
 147 layers. The simulation in the medium M_{app} is carried out with the same
 148 geometry, but with a homogeneous velocity of 2000 m/s.

149

150 The synthetic data (vertical component) are shown in figure 2a. Even
 151 though the explosive source only produces P-waves, the wavefield above the
 152 interface contains S-waves, generated by the P-to-S conversion at the inter-
 153 face, with amplitudes stronger than the transmitted P-waves. In the model
 154 M_{app} , the explosive source produces only P-waves, whilst a vertical force at
 155 such large take-off angles mainly generates S-waves (fig. 2b). The wave-
 156 forms in fig. 2a looks very similar to the sum of the waveforms in fig 2b.
 157 Qualitatively, it seems that, to reconstruct the seismic waveforms generated
 158 in the two-layer medium, SFs are needed in the homogeneous medium in
 159 order to fit the high energy converted waves. Using the inversion process
 160 previously described, the misfit decreases from 51 % when an explosion only
 161 (Ex) is considered in eq. (1) to 12 % ($\alpha_F=4.2$ and $\alpha_{Ex}=1$) when a verti-
 162 cal SF is included (Ex&Fz) in the inversion. Since they are no single forces
 163 in the original data for the two layered medium, these large SFs are spurious.

164

165 We investigate the variations in amplitude of the apparent SFs as a func-
 166 tion of the contrast between the two layers, by changing the velocity V_{p1} in
 167 the top layer. The misfit between the reconstructed and synthetic data is
 168 given in fig. 2c, and fig. 2d shows the normalised amplitude of the explosion

α_{Ex} and SFs α_F required in the approximate model. As expected, when there is no contrast, no SFs are found. When $Vp_1 > Vp_2$, although significant SFs can be found, the misfit does not change much whether or not SF are included. In contrast, the amplitude of the SF strongly increases when $Vp_1 < Vp_2$ (i.e. low velocity layer on top of the volcano), leading to a misfit value roughly constant for Vp_1 between 1400 and 2600 m/s. When Vp_1 is even lower, strong SF are still found, but the waveform reconstruction deteriorates. These simple examples show that the presence of a mismodeled low velocity layer on the top of the volcano will lead to strong SF in the mechanism reconstruction with a high misfit difference between inversion with and without SF. As the layers in a volcano are certainly not horizontal, strong horizontal SFs might also be reconstructed to accommodate converted waves.

The similarity of the response between the amplitude of the P-to-S converted waves and the Fz radiation pattern can be illustrated by comparing the theoretical AVA (Amplitude Versus Angle) response of i) an explosion in the two-layer medium M_{True}^1 , and ii) of a vertical SF and an explosion in the homogeneous medium M_{app} , for both P and S waves (fig. 2e). This brings into play the radiation patterns of the source, the transmission coefficients and the geometrical spreading, as defined in Aki and Richards (2002). The angle is defined as the $\arctan(Xs/Zs)$, where Xs and Zs are the horizontal and vertical offset from the source, respectively. It corresponds to the incidence angle only in the homogenous case. In the medium M_{app} , P-waves are coming from both the SF and the explosion, and S-wave are generated by the SF only. Both P transmitted and S converted waves generated by the ex-

194 plosion in the 2-layer medium have amplitudes that can be fitted remarkably
 195 well with an explosion and a SF in the homogeneous medium, especially for
 196 angles less than 50° . The amplitudes of the waves in the "true" and in the
 197 "approximate" medium are still very similar for higher angles.

198

199 3.2. Source mislocation

200 A similar analysis is performed to evaluate why SFs appear in MTI when
 201 the source is mislocated (fig. 1b). Synthetic data are computed in the homo-
 202 geneous model M_{True}^2 with a free surface and a source located at 200 m depth
 203 (tab. 1). This model is approximated by the model M_{app} , with the source at
 204 400 m depth, i.e. vertically mislocated by 200 m. Figure 3a shows the dataset
 205 calculated from an explosive source in both media. While P-waves look very
 206 similar, surface waves and S-converted waves at the surface strongly differ in
 207 amplitude. When a vertical SF is included in the model M_{app} (fig. 3b), the
 208 waveform fit is far better, with a misfit decreasing from 37% (Ex only) to
 209 16% (Ex&Fz). The SF amplitude is once again very strong, with $\alpha_{Ex} = 1.1$
 210 and $\alpha_F = 2.9$.

211

212 We then modify the source depth Z_{true} from 0 to 800 m in the model M_{True}^2
 213 (see Fig. 3c and d), while the source location in the M_{app} model is kept at
 214 400 m depth. When the source in M_{app} is shallower than Z_{true} (i.e $Z_{true} >$
 215 400 m), SFs are not reconstructed. On the other hand, for shallow sources
 216 mis modeled by deeper ones (i.e $Z_{true} < 400$ m), the amplitudes of the SF
 217 increase with the depth errors and the misfit difference between Ex only and
 218 Ex&F reconstructions is quite strong. Hence, vertical SFs are found when

219 the source depth is over estimated. In the presence of topography, horizontal
 220 SFs may also be required to compensate for an imperfect source location, as
 221 shown in fig. 1.

222 3.3. Other frequency range

223 In order to generalise our findings to a broader frequency range, we carry
 224 out the same two tests as described in Sect. 3.1 and 3.2, for a suite of source-
 225 time functions (Ricker wavelets) with the central frequency ranging from 0.05
 226 to 2 Hz. The results are given in Figure 4. For the VLP wavelet ($F_{peak}=0.05$
 227 Hz) without the inclusion of SFs, velocity mismodeling and mislocation re-
 228 sult in a small misfit between the synthetic and reconstructed data (0.25%
 229 and 4%, respectively, Figs. 4a and c). This is because the travel time dif-
 230 ferences caused by different velocity models and/or locations are negligible
 231 compared to the dominant period of STF. When a vertical SF is included,
 232 the misfits decrease to 0.07% and 2.2%, respectively, that is, by a factor of
 233 2-5. Although the absolute values of these decreases are small, spurious SFs
 234 of relatively large amplitudes are reconstructed, with $\alpha_F=0.3$ and $\alpha_F=-1.5$
 235 for the mismodeling and mislocation case, respectively (Figs. 4b and d) .

236
 237 Such a result is in agreement with Ohminato et al. (1998) and Chouet
 238 et al. (2003) for the mislocation case, even if they consider much smaller
 239 source location errors or deeper source. For the velocity mismodeling case,
 240 they both used homogeneous models with different velocities to compute
 241 Green's functions and synthetic data. They found that no or very small spu-
 242 rious SFs are reconstructed. We agree with these authors that VLP inversion
 243 are not sensitive to a wrong homogeneous velocity. However, we showed here

244 that spurious SFs are generated to accommodate converted waves at layer
245 interfaces, which were not present in their tests. Our approach suggests that,
246 at all frequencies, both velocity mismodeling and source mislocation can re-
247 sult in strong spurious SFs, which can heavily contaminate the real single
248 forces, if they exist.

249 4. Discussion and conclusion

250 Using simple numerical examples, we showed that strong SFs are required
251 to compensate for velocity mismodeling and source mislocation, for both LP
252 and VLP signals. These examples are obviously too simple to reproduce the
253 complexity of the seismic wavefield recorded in a volcanic environment, but
254 they do capture the essence of the problems we face in terms of poor source
255 locations and poorly constrained very near-surface velocity structure. They
256 illustrate how spurious SFs are required in order to reconstruct the observed
257 converted and surface waves, produced by an interface or the free surface.

258
259 As the sources of the non-shearing volcanic seismicity are usually very
260 shallow, take-off angles are large. Hence, a vertical SF mainly generates
261 S-waves at the recording stations. If the medium is approximated with a
262 smooth or homogeneous medium, converted P-to-S waves at any interfaces
263 are not modeled and are accommodated by apparent SFs in the source. In
264 particular, low velocity layers have been commonly observed on the top of the
265 volcano, for examples on Mt Etna (Cauchie and Saccorotti, 2013), Vesuvius
266 (Saccorotti et al., 2001) and Arenal (Mora et al., 2006). They are usually
267 not considered in MTI. A location error of a few hundred meters is more the

rule than the exception in volcanic environments, and can lead to spurious SFs, to accommodate converted S-waves and surface waves. In both cases, the spurious SFs produce waves with comparable amplitudes as those from the MT part of the solution.

Since shallow layers are usually not known, it may be useful to use SFs in MTI to accommodate errors arising from unmodeled layers (De Barros et al., 2011). However, such an approach requires a high-resolution seismic network, otherwise the MT solution might not be correctly reconstructed (Bean et al., 2008). In cases where SFs are actually real, they will be corrupted by strong spurious SFs which inevitably exist as demonstrated herein. Their physical processes cannot be unambiguously interpreted. On the other hand, the presence of strong SFs may give an indication of the presence of a layered structure and the best source location may be where the inversion misfits with and without forces are similar.

The misfit difference between MTI with and without SFs may be quite large and comes from the mismodeling and not from inversion for the sources itself. Hence, the misfit cannot be used directly or through Akaike or BIC criteria to determine if SFs should be used in the inversion (O’Brien et al., 2010). We recommend that synthetic tests as outlined above with mismodeling are undertaken in order to decide whether SFs should be included or not. As the source locations are shallow, stations above the source area are required to stabilize the inversion and achieve lower amplitude spurious SFs. Furthermore, as already noted by Bean et al. (2008), improving the source

293 mechanism reconstruction will firstly require improvements in velocity mod-
294 els, especially in the shallow parts of the edifice.

	SRC	Zsrc (m)	Vp (m/s)
M_{True}^1	Ex	400	1600/2400
M_{True}^2	Ex	200	2000
M_{app}	Ex/Ex&Fz	400	2000

Table 1: Velocity models used in this study. M_{True}^1 (layered model) and M_{True}^2 (shallow source model) are the “true” models, and M_{app} is the “approximate” model (equivalent to the medium where the GFs are computed in a MTI). The data computed in the true models with an explosive source are reconstructed using data generated in the model M_{app} by i) an explosion only (Ex) or ii) by an explosion and SF (Ex&F). Zsrc denotes the source depth, while V_P is the P-wave velocity used in the calculation. The 12 receivers are at Z=0, with horizontal offsets ranging from 250m to 3000m from the source.

Figure 1: Solutions of the Moment Tensor Inversion of synthetic data computed for a vertical crack source ($M_{xx}=3*M_{yy}=3*M_{zz}$) in the Mt Etna geometry. a) Data computed in a layered medium and inverted with GFs calculated in a homogeneous medium; b) Data computed in homogeneous medium and inverted with GFs calculated for a source mislocated by 120 m downward and 90 m horizontally. For both cases, gray thick lines are the true solutions and the black lines are the reconstructed solution for the 6 moment components and the 3 SFs.

Figure 2: Apparent SFs generated by a velocity model error. a) Synthetic “True” data computed in the two-layer model (M_{True}^1 , with $V_{p1}=1600$ m/s and $V_{p2}=2400$ m/s), with an explosion located 200 m below the interface. No free surface is included. Receivers are 200 m above the interface. b) Waveforms computed in the medium M_{app} for an explosion (thick line) and a vertical SF (thin red line). Note that each trace is normalized in a) and b). c) Misfits in the reconstruction using an explosion only (Ex) and an explosion and a vertical force (Ex&Fz), as a function of the velocity V_{p1} in the model M_{True}^1 . d) Amplitude of the explosion (left scale, α_{Ex}) and the SF Fz (right scale, α_F) for the Ex only and the Ex&Fz reconstruction. e) Theoretical Amplitude Versus Angle (AVA) response for an explosion and a vertical SF in the homogeneous medium M_{app} , and transmitted P- and S- waves generated by an explosive source in the 2-layer medium M_{True}^1 .

Figure 3: Apparent SFs generated by an incorrect source location. a) Synthetic data computed in the “true” model (M_{True}^2) with an explosive source located at $Z_{true}=200$ m (thick lines) and in the “approximate” medium M_{app} with an 400m-deep explosive source (Ex) (thin red lines). b) Same as a) with explosive and vertical SF (Ex&Fz) sources in the model M_{app} . c) Misfit between the two data-sets using Ex only or Ex&Fz in the model M_{app} , as a function of the depth Z_{true} of the source in the “true” model. d) Amplitude of the explosion (α_{Ex} , left scale) and the force Fz (α_F , right scale) for the reconstruction using an explosion only (Ex) only and an explosion and vertical force (Ex&Fz).

Figure 4: Generation of spurious SFs as a function of the peak frequency F_{peak} of the source time function (Ricker wavelet). Velocity mismatching case (same set-up as for fig. 2): a) misfit between the synthetic data and the reconstructed waveforms using an explosion only (EX, solid line) and an explosion and a vertical SF (EX+SF, dashed line), b) the amplitude α_F of the vertical SF. c) and d) are the same as a) and b) but for the source mislocation case (same set-up as for fig. 3). Note that the spurious SF changes sign with the increasing frequency, and is therefore null for $F_{peak}=0.35$ Hz.
