Since the first reports some three decades ago, the chemistry of pincer metal complexes has seen a
tremendous development with impact on materials chemistry, supramolecular chemistry,
bioorganometallics, and, presumably most significantly, on (catalytic) bond making and breaking
processes. The remarkable progress is due to a large extent to the well-defined nature and
mutability of the pincer ligand which allows the reactivity of the metal center to be modified and
eventually tailored to specific needs. This Perspective summarizes the achievements in employing
pincer complexes for mediating and catalyzing the cleavage of typically unreactive bonds such as
C–H, C–C, C–E, and E–H bonds, arguably one of the most spectacular applications of pincer
chemistry.

Introduction

Pincer ligands have become extraordinarily useful scaffolds for directing specific reactivity patterns of metal centers for a
large variety of applications, for example as highly efficient sensors, switches, and catalysts.1 Pincer ligands are typically
characterized by a monoanionic E,C,E-terdentate bonding mode where C denotes a central carbanion, often an aryl
anion, and E represents a neutral two-electron donor such as an amine, imine, phosphine, phosphinite, sulfide or selenide (Fig 1). In general, these ligands adopt a meridional
coordination mode,2 and as a consequence, the M–C bond in pincer complexes is effectively shielded and considerably
stabilized as compared to other M–C bonds. As a consequence, the high trans effect of the anionic central
ligand can be fully exploited in pincer complexes.

Furthermore, the electron density at the coordinated metal center may be altered and eventually tailored by selective
ligand modification, which does not affect the general bonding mode of the ligand, e.g. via introduction of electroactive groups on the aryl ring (R’) or on the heteroatom
E.

![Fig. 1. General representation of an ECE pincer ligand coordinated to a metal fragment (MX3n), including the different functions that can be regulated by appropriate ligand modifications.](image)

Various modifications have been implemented on the general pincer scaffold, including the substitution of the central
carbanion by an amide (NR2) or a silyl anion.3 Similarly, the linker between the core unit and the donor arms has been
changed from an sp2- or sp3-hybridized carbon to oxygen.

Some of these modifications are accompanied with a significant decrease of the chemical stability of the ligand
scaffold towards degradation, and ligand fragmentation has been observed in several cases.4

In part due to their high modularity, various pincer metal complexes have been developed that enable challenging bond
making and breaking.5 In some cases, the rigidly chelating bonding mode has been exploited to stabilize crucial
intermediates, and to provide mechanistic insights. In other cases, the variability has been crucial for imparting high
catalytic activity. While significant progress in cross-coupling catalysis has been achieved and reviewed,6 perhaps the most
remarkable results have been accomplished in the activation and cleavage of typically unreactive bonds, such as C–H, N–
H, and O–H bonds, and also C–C and C–heteroatom bonds.7 This Perspective aims to overview the most significant
advances, both in terms of mechanistic understanding and catalytic performance of pincer metal complexes in cleaving
such unreactive bonds. An excellent review has appeared recently on PCP iridium-catalyzed dehydrogenation of alkanes
and amine boranes,7 and these reactions are thus not discussed in any depth here. Similarly, the iridium-mediated formation of
carbones from the activation of methyl ethers and amines via double α-H elimination, and ensuing catalytic applications
have been summarized in a recent account.8,9

Activation of C–H bonds

Dehydrogenation of unactivated alkanes has been most efficiently performed with PCP iridium complexes as catalysts
and turnover numbers up to 3000 have been achieved with optimized pincer scaffolds.7 The working mode of the catalyst
has been thoroughly investigated by kinetic and theoretical studies, and concurrent isomerization reactions as well as
product inhibition effects have been identified. An analogous PCP rhodium complex comprising an agostically bound
methane molecule, long postulated as a crucial intermediate of
the catalytic cycle, has recently been isolated and structurally
characterized.10

...
Cleavage of activated C(sp^3)-H bonds

The PNP iridium(III) complex 1 activates a C–H bond of acetone stoichiometrically (Scheme 1). In this complex, the ligand is not aromatic and comprises an exocyclic double bond. Aromatization is induced upon protonation of the benzylc position, which also transforms the anionic amide donor into a neutral pyridine system. This aromatization is reversible and deprotonation of 2 has been demonstrated to occur at the benzylc position, thus reverting the formally monoanionic PNP pincer chelate. Cooperative participation of the ligand in the C–H bond activation of acetone has been postulated, involving the addition of the C–H bond across the metal-ligand unit. Deuterium labeling studies support a stepwise process including initial oxidative C–H activation at the benzylc position of the ligand with concomitant aromatization. Theoretical analyses (DFT) support the proposed mechanism and predict the tricoordinate PNP iridium complex A as a critical intermediate.

![Image](image_url)

**Scheme 1.** PNP iridium-mediated activation of acetone.

The propensity of these PNP-type pincer ligands in cooperating in bond activation processes has been further exploited in the Ru-catalyzed dehydrogenative coupling of alcohols (Table 1). In the presence of primary amines, either imines or amides are formed, depending on the donor sites at the pincer ligand. With the PNP ruthenium(II) complex 3, imines are produced, while the PNN analogue 4 affords amides. In either system, the dehydrogenation activity of the ruthenium pincer complex is critical for high catalyst activity. Both imine and amide formation have been proposed to be sequential processes involving first dehydrogenation of the primary alcohol to the aldehyde, and subsequent reaction with the amine. Generally, a Schiff base-type reaction ensues, thus producing imines. The selectivity of complex 4 to generate amides thus implies that the carbonyl group remains coordinated when attacked by the amine, hence forming the hemiaminal within the ruthenium coordination sphere. Alternatively the hemiaminal intermediate of the Schiff base reaction may bind to the ruthenium center after being formed. In either case, an intermediate B is proposed, which can undergo a second dehydrogenation involving C–H bond cleavage to afford the amide product (Scheme 2). The mismatch in the PNN ruthenium complex between the soft metal center and the hard amine unit increases the hemilability of the pincer ligand and thus favors carbonyl coordination and hence amide formation. In contrast, the two soft phosphine donors in the PNP ligand bind stronger to ruthenium and P–Ru dissociation is disfavored. Hence, this complex releases the carbonyl intermediate rapidly and the reaction with the amine occurs as under normal Schiff base conditions to generate imines selectively. In agreement with this mechanistic proposal, secondary alcohols are less reactive and secondary amines are not incorporated at all.

**Scheme 2.** Proposed catalytic cycle for the dehydrogenative coupling of alcohols and amines to form imines or amides.

In the absence of reactive amines, homocoupling of alcohols becomes the predominant pathway with complex 4 or 5. With less bulky substituents at the pincer donor groups, esters are formed, while sterically congested metal centers as in 5 lead to the predominant formation of acetals. Efficient ester formation from alcohols requires the addition of a base. Along similar concepts, catalytic transesterifications have been successfully accomplished upon reacting esters and...
primary alcohols in the presence of complex 4. The PCP iridium complex 6 is an efficient catalyst for the oxidation of primary amines to nitriles (Scheme 3). Efficient double dehydrogenation has been achieved in the presence of tert-butylethylene as sacrificial hydrogen acceptor. Detailed mechanistic work involving a combination of competition experiments, isotope labeling studies, and kinetic analyses have identified three potential resting states of the catalyst, 6, 7, and F, which are interconnected via two pre-equilibria. Not surprisingly, a hard step is the substitution of the nitride product from the coordination sphere of complex 7 by a new amine substrate (K \( \sim \) 550). Subsequent reversible N–H oxidative addition is followed by β-hydrogen elimination to produce G as the rate-limiting step, indicated by the substantial kinetic isotope effect of 2.8(2).

Cleavage of C(sp^3)–H bonds

Cyclometalation is typically supported by initial heteroatom coordination followed by C–H bond activation.

Since pincer ligands contain two such potential anchoring sites for metal coordination, metal-mediated activation of the C_{sp^3}–H bond in the ligand precursor is very common in pincer chemistry and represents one of the oldest and most frequently used strategies to introduce the metal center. Here, only special cases are highlighted, such as C–H bond activations that are not heteroatom-assisted or that are incomplete and allow relevant intermediates to be stabilized and investigated.

Upon coordination of a second PCP ligand to the PCP ruthenium complex 8, the agostic intermediate 9 has been isolated. This complex features one cyclometalated PCP ligand and one P,P'-bidentate coordinating H–PCP ligand (Scheme 4). Crystallographic analysis strongly suggests an agostic interaction between the ruthenium center and the C–H bond of the non-cyclometalated ligand. In solution, NMR spectroscopy has indicated a resonance of this proton at 1.2 ppm, thus being magnetically neither a hydride nor an aryl-bound hydrogen. Extensive \(^{31}\)P NMR spectroscopic investigations and isotope labeling experiments have revealed a dynamic behavior of this hydrogen nucleus, involving migration from the non-cyclometalated ligand to the cyclometalated one. Further evidence for such proton migration has been obtained upon introducing a substituent on one of the arene fragments (9b, X = Br), which allows the two PCP ligands and hence complexes 9 and 10 to be differentiated. Base-mediated abstraction of the fluxional proton has been unsuccessful.

Scheme 4. Agostic interaction in a PCP ruthenium complex.

A structurally related agostic complex that may be regarded as a stabilized intermediate of a cyclometalation reaction has been isolated from [Rh(CO)(C\(_2\)H\(_5\))(solv)]\(_2\)OTf and different PCP ligand precursors (Scheme 5). Complex 12 features an agostic interaction involving \( \sigma^* \)-coordination of the C–H bond to the rhodium(I) center. This bonding mode, confirmed by X-ray crystallography, is preserved in solution as indicated by the unusual chemical shift of the ipso proton (\( \delta_H \) 4.1 ppm) and its magnetic coupling to the rhodium center. The substantial upfield shift suggests that the proton has lost its aromatic character. Analogous products form when the central arene unit is functionalized with methoxy substituents. Apparently, the major metal-ligand interaction is due to the agostic interaction rather than due to an arenium-type limiting resonance form. In an agostic structure, the positive charge is formally located on the metal center, and not on the ligand as in arenium-type species. A rationale for this observation may rely on the fact that rhodium(I) is electron-rich and relatively soft, favoring \( \pi \)–backbonding rather than \( \sigma \)-donor interactions with ligands. In related complexes containing more electrophilic palladium(II) and platinum(II) centers, the arenium structure seems to contribute stronger (see below). In contrast to complex 9, the proton in 12 is acidic and has been successfully abstracted with a weak base in order to complete the cyclometalation process, thus yielding the PCP rhodium complex 13. It is worth noting that slight modifications in the metal precursor markedly decrease the stability of complex 12. With [RhCl(CO)\(_2\)]\(_2\), for example, the PCP ligand precursor 11 undergoes rapid cyclometalation to give 13 as the exclusive product.
Apart from these mechanistic insights involving intramolecular C–H bond activation of the pincer ligand itself, numerous studies report on intermolecular activation of C(sp³)–H bonds. A PNP ruthenium polyhydride complex has been shown to cleave aromatic C–H bonds reversibly. This reactivity pattern has been employed for catalytic H/D exchange using C₆D₆ as deuterium source. 

Ligand cooperativity as evidenced in PNP and PNN pincer complexes is an attractive concept, and it is tempting to invoke C–H bond activation by a) oxidative addition (insertion) followed by optional reductive elimination (nucleophilic M); b) by substitution, including bond metathesis and electrophilic pathways.

Upon combining these seemingly different concepts, a detailed and comprehensive model of the pincer-metal mediated C–C bond activation process emerges (Scheme 7). Many intermediates of this process have been characterized spectroscopically, and often also crystallographically. Two conclusions are probably most relevant: firstly, the intrinsic step of C–C bond making and breaking appears to be highly similar in oxidative addition and substitution-type reactions. Secondly, mechanistic investigations on C–C bond formation and on C–C bond cleavage provide a converging picture, which suggests a common reaction coordinate.

**Mechanistic investigations**

Phosphine-containing PCP, PCN, and PCO pincer ligands have been used in combination with rhodium and iridium to study mechanistic aspects of C–C bond cleavage, while NCN platinum systems allowed for the stabilization of intermediates during C–C bond formation. In rhodium(I) and iridium(I) chemistry, an oxidative addition pathway for C–C bond activation has been discussed extensively, while a substitution process has been put forward for platinum(II) complexes (Scheme 6). Theoretical considerations support this general picture, yet it should be noted that despite the difference in terminology, the overall reaction coordinate of both substitution and oxidative addition are highly similar.

Distinction often requires evoking minor differences in metal-ligand and ligand-ligand interactions.

### Activation of C–C bonds

While C–C bond formation is a mature field, most notably due to the significant advances in metal-mediated cross-coupling reactions, the reverse process, i.e. C–C bond cleavage, is still at its infancy. Pincer complex formation has been used as a driving force to entail alkyl-aryl C(sp³)–C(sp³) bond cleavage. Mechanistic investigations on the C–C bond activation process and also on its microscopic reverse, viz. C–C bond formation, provided insights into the intimate steps of the bond cleavage process and several crucial intermediates have been stabilized due to the unique steric and electronic impact of the pincer-type ligands.
compared to C

Similarly, replacing one phosphine donor by a harder NEt

Metalation of the PCP ligand precursor

Metalation of the PCP ligand precursor 16 with a rhodium(I)
salt results in Caryl–alkyl and Calkyl–H bond activation

Only at elevated temperatures and under H2 atmosphere, C–C
bond activation is observed. In contrast bulky P'Bu3 donors
promote C–C bond activation already at room temperature and
the aryl complex 18 is the exclusive metatalated product.
Similarly, replacing one phosphine donor by a harder NEt2
or employing less basic phosphinite donors results in
fast and exclusive C–C bond cleavage at room temperature
and below. These outcomes indicate that steric rather than
electronic effects play a dominant role for the thermodynamic
preference of C–C over C–H activation. Steric congestion has
been suggested to force the metal orbitals into a rigid
orientation that is directed towards the C–C bond. Moreover,
the C–H bond activation is reversible while the C–C
activation is not, unless chemically induced, e.g. by
phosphine-induced metal dissociation.

The higher bond dissociation energies required for C–C bond activation as compared to C–H bond breaking is evidently compensated by

The stability of the intermediates is highly dependent on the
nature of the metal center and the donors E, and an
intermediate in one M/E set may become a transition state in a
different metal/ligand combination. For example, in NCN
platinum chemistry (E = NMe2), intermediates J and L have
been characterized, while structure K is supposed to be the
transition state in between. Complexes of type K are more
stable in PCP rhodium complexes and have been isolated as
an intermediate of C–C bond activation. Likewise, the
coordination compound I has been postulated as a short-lived
intermediate in PCP rhodium complexes. Upon changing the
donor array to a PCN pincer ligand, this species is sufficiently
stable to be characterized.

Postulated mechanism of C–C bond making and breaking
within a pincer scaffold.

Scheme 7. Postulated mechanism of C–C bond making and breaking
within a pincer scaffold.

Scheme 8. Reversible C–H and irreversible C–C bond activation in rhodium complexation of PCP ligand precursors.

Kinetic investigations of these reactions have identified the
coordination compound M, i.e. an analogue of I (cf Scheme
7), as a common intermediate of both, C–H and C–C bond
cleavage. Remarkably, formation of this intermediate, and not
C–H or C–C bond activation is rate-determining. While
displacement of a weakly bound olefin ligand in the rhodium
precursor [RhCl(olefin)2]2 may be fast, formation of the 8-
membered metatalcyle in M is obviously less favored,
especially due to the possible formation of di- and polymeric
coordination compounds. With appropriate donor groups, the
postulated coordination complex akin to M has been
characterized in solution at low temperature. When using
kinetically less reactive platinum(II), the bidentate
diphosphine coordination is even further stabilized.

The transoid bidentate chelation of the donor groups in M is
pivotal for entailing C–C bond activation. When using
monophosphine ligand precursors that lack a second donor
C–H bond activation occurs selectively and no C–C
bond cleavage has been observed. With the related PCO
pincer ligand precursor 19, C–H activation is kinetically
preferred at room temperature (Scheme 9).

However, this reaction is not selective and produces a mixture of 20 and 21, indicating that both C–H bonds in ortho position to the
phosphine are activated. Upon heating, C–C bond activation
takes place exclusively at the position ortho to both the O and
P donor groups to afford 22. These reactivity patterns illustrate the reversibility of C–H bond activation process, and more importantly, that bidentate ligand bonding is essential for C–C but not for C–H bond activation. Furthermore, these
conclusions provide a rationale for the inherent difficulties
encountered when probing catalytic or intermolecular C–C
bond activation. Undoubtedly, though, the potential to
accomplish and (thermally) trigger the activation of such
otherwise unreactive bonds illustrates the extraordinary
potential of pincer-type chelation for tuning unique metal-
mediated processes.

Journal Name, [year], [vol], 00–00 | 5
The activity of the rhodium center in intermediate M towards C–H bond cleavage is strongly associated with its tricoordinate 14e configuration. Consequently, the bond activation process reveals a strong solvent dependence. In coordinating MeCN, stabilization of the rhodium center and the formation of square-planar complexes depletes the concentration of the 14e intermediate, and C–H bond activation becomes the predominant reaction pathway. Conversely, less coordinating solvents such as tetrahydrofuran favor C–C bond cleavage.

Similarly, substitution of the metal center from rhodium to iridium, ruthenium, or platinum has direct consequences.

While activation of the C–C bond in the PCP ligand precursor 16 occurs smoothly at room temperature with rhodium(I), only C–H bond activation is observed with the iridium(I) homologue. Substantial heating is required to direct the course of the reaction towards C–C bond activation. These results underline the increasing stability of Ir–hydride species compared to their Rh analogues, and presumably also the higher nucleophilicity ascribed to the rhodium(I) center.

The strong influence of the metal on the C–C vs C–H bond activation selectivity is further illustrated in osmium(II)-mediated C–C bond cleavage. Exposure of [OsCl₂(PPh₃)₃] to the hydroxy-functionalized PCP ligand precursor 23 containing basic PPr₃ donors induces Cₓaryl–Cₓalkyl bond cleavage and yields complex 24, when the reaction is performed in the presence of H₂ (Scheme 10). In the absence of H₂, the quinone methide 25 is formed selectively as a result of C–H bond activation. A dynamic process has been suggested that involves interconversion of the quinone methide 25 to its arenium tautomer N, resulting from insertion of the exocyclic olefin into the Os–H bond. An analogous product has been trapped upon addition of CO. A subsequent shift of the methyl group to osmium followed by hydrogenation of intermediate O has been postulated to account for the formation of complex 24, thus suggesting the quinone methide 25 to be an early intermediate in the direct formation of 24 from 23.

Arenium complexes have been extensively studied earlier in NCN platinum chemistry. They are readily prepared from the solvento complex 26 and are resistant towards air and moisture. The crystal structures of several complexes show consistently that the platinum center is bound to the aryl carbon only. In all structures, the Pt…Cₓaryl distance is far too large for postulating any agostic resonance structure contribution (cf K in Scheme 7). In addition, these platinum-stabilized arenium complexes readily react with nucleophiles at their ortho and para position and afford platinum-substituted cyclohexadienyl derivatives. This deamination process indicates that the positive charge is localized on the aromatic ring rather than on the metal center. Arenium structures have been proposed to result from a 1,2-sigmatropic shift of the alkyl group from the metal center in the (alkyl)(aryl) complex 27 to the aryl carbon in 28 (Scheme 11), thus relating structures J and L directly (cf Scheme 7). Spectroscopic identification of this migration has been achieved by incorporating electron-donating substituents on the aryl ring (R = OH, OMe), a well-known concept in electrophilic aromatic substitution. Such a modification increases the reactivity of the ipso carbon and of the platinum center in 26 and allows (alkyl)(aryl) complexes to be stabilized with a variety of different alkyl substituents other than MeI. In the case of the (benzyl)(aryl) complex 27, a color change has been observed upon formation of 28. Analysis of this transformation by UV-visible spectroscopy has revealed an isosbestic point, thus indicating the presence of an equilibrium between the two species 27 and 28 exclusively. This equilibrium implies that alkyl migration between 27 and 28, viz. the microscopic C–C bond making and breaking step, is fully reversible. Consequently the actual C–C bond formation is the exact microscopic reverse of the C–C bond cleavage process in these platinum pincer complexes.
This journal is © The Royal Society of Chemistry [year]

The alkyl group migration has been postulated to include a 3-centered non-polar transition state reminiscent to I (cf. Scheme 7). Molecular orbital considerations suggest two distinct interactions that contribute predominantly to the stability of K. One interaction (Fig 3a) is characterized by overlap of an sp³ orbital of the formally cationic alkyl group with the filled dₓ orbital of the d² metal center, having predominant dₓz character, and simultaneous interaction with the distorted pₓ orbital of the aryl carbon. Shutting of the alkyl cation from the metal closer to the carbon obviously increases C–C bond overlap and thus induces a rehybridization of the pₓ orbital to an sp³ orbital, and dearomatization ensues upon C–C bond formation, leading to areniunium structures. The microscopic reverse C–C bond cleavage process thus includes the metal-induced depletion of electron density in the C–C bond, a process that is favored with electrophilic metal centers such as platinum(II).

A second contribution consists of a metal d, electron donation into the C–C σ* orbital bond and leads to an agonistic interaction that eventually climaxes in an oxidative addition (Fig 3b). Stronger donor ability of the ligands E and electron-rich, nucleophilic metal centers such as rhodium(I) or iridium(I) will thus increase the electron density in the C–C antibonding orbital (σ* backbonding) and C–C bond cleavage along this reaction coordinate will be facilitated. These considerations may explain the different stability of the intermediate complexes in NCN platinum(II)-mediated C–C bond making and breaking as opposed to analogous processes at PCP iridium(I) and rhodium(I) centers. The former stabilizes areniunium species due to strong C–M σ interactions with the electrophilic platinum(II), while the latter prefer an agonistic bonding mode that allows the nucleophilic metal centers to be bound to a π*-accepting ligand.

In agreement with this model, stabilization of an agostic complex has been achieved by appropriate modification of the donor group (29, Fig 3e). Upon substitution of one phosphine donor by a NEt₂ group, the electron density at the cationic rhodium center is reduced to such an extent that the agostic complex is moderately stable and thus does not represent a transition state anymore. The electronic balance which determines whether C–C bond activation is completed or arrested at the agostic stage is very subtle. Using [Rh(C₂H₅)₂(solv)]⁺ rather than [Rh(CO)(C₂H₅)(solv)]⁻ as metal precursor leads to clean C–C bond cleavage.

**Methylene Transfer**

Interesting synthetic opportunities emerge from reactions that are under kinetic control, leading to products from C–H rather than C–C bond activation. For example, complexation of rhodium(I) with the CH₂–PCP ligand precursor 16 bearing PPh₃ donors induces C–H bond activation and affords the benzyl complex 30 (Scheme 12). The corresponding platinum(II) complex with a coordinated [PtCl] unit—isolo- to the [Rh(PPh₃)] fragment—has been prepared even with bulky PPh₃ groups in the pincer scaffold. In these complexes, C–C bond activation has been induced by addition of H₂ or HCl. Apparently, H₂ and HCl favor regenerative C–H elimination, i.e., the backward reaction from C–H bond activation and formation of the intermediate Q (Scheme 12, see also 1 in Scheme 7). Simultaneously, the activation energy for C–C bond activation is reduced, rendering C–C bond activation more favorable than C–H bond activation. The overall process from 30 to 31 may formally be considered as a CH₂ transfer to an appropriate acceptor such as H₂ or HCl, leading to the production of CH₄ and CH₃Cl, respectively. Similarly, benzene, hydroisilanes, and disilanes have been successfully employed as acceptors, providing toluene, R₃SiCH₃, and R₃Si–CH₂–SiR₃, respectively.

---

Scheme 11. Reversible areniunium formation in NCN platinum complexes.

**Fig. 3.** a) Orbital interactions relevant for C–C bond activation via sigmatropic 1,2-shift of a cationic alkyl fragment along the C–M bond (electrophilic activation, electron removal from the C–C σ orbital); b) agonistic interaction en route to oxidative addition (population of the C–C σ* orbital via backbonding); c) complex 27 as a structural model comprising agonistic interactions.
addition of the acceptor E–R to the benzyl complex (P, Scheme 12).
Rate-limiting C–R reductive elimination and subsequent C–C bond activation is followed by irreversible reductive E–CH₂R elimination from R, thus completing the CH₂ transfer and affording the PCP rhodium complex 31. Notably, Rh–phosphinite complexes reminiscent of R have been shown to undergo apparent α-hydrogen elimination, thus providing an alternative mechanism for the release of the CH₂ fragment (for R = H).

The absence of any products originating from double CH₂ insertion indicates that C–aryle–Calkyl bond activation is an intramolecular process. The methylene transfer reaction can be reversed by addition of CH₃I as the CH₂ acceptor molecule as the rate-determining step of this reaction. Consistently, the use of an aryl halide promotes fast oxidative addition to 30 already at room temperature (Scheme 13). The formed complex 32 undergoes a methylene transfer at slightly elevated temperatures to yield the (benzyl)(aryl) complex 31. This complex is also accessible from the PCP rhodium complex 31 via oxidative addition of substituted benzyl bromide. Reductive elimination from 33 is initiated only upon addition of a coordinating ligand such as PPh₃ and a carbanion R’CH₂ as nucleophile, presumably via transmetalation and formation of the postulated triorgano-rhodium complex S. Several competing reactions then ensue: cross-coupling of the two monodentate ligands gives complex 31 as the organometallic product. Alternatively, one of the monodentate carbanions may reductively migrate to the pincer ligand ipso carbon to produce an intermediate similar to 1 (cf Scheme 7), corresponding to a back transfer of the methylene group. Upon C–H bond activation, complexes 34 and 35 are obtained via migration of the nucleophile and the benzyl group, respectively. Variation of the substituent R at the benzyllic group has evidenced a strong electronic control. Electron-releasing groups (R = OMe) increase the migration tendency and yield predominantly 35, whereas acceptors (R = CF₃) migrate slower and hence produce 34 and significant amounts of cross-coupling products.

Scheme 13. Methylene transfer and cross-coupling mediated at a PCP rhodium center.

Activation of C–E bonds

The catalytic activity of pincer complexes in cross-coupling reactions implies a high potential of these complexes to activate C–B and C–Si bonds used for Suzuki-Miyaura and Hiyama-type reactions, respectively, and of course a wealth of C–X (X = Cl, Br, I, OTf) and C–M bonds (M = Mg, Al, Sn, Zn, etc.). Here, only strong C–E bond activation will be discussed, including cleavage and redox reactivity of C–N, C–O, and C–F bonds.

C–N bond activation

Metal-mediated C–N bond activation is little explored in pincer chemistry. Activation of a Cbently–N bond in a pincer-type ligand precursor has been observed in the presence of [RhCl(coe)₂]₂ and H₂. While the reaction is catalytic (up to 21 TONs), the mechanism has been postulated to not involve pincer-type metal bonding. A PNN ruthenium complex related to 1 (cf Table 1) catalytically cleaves amides to amines and alcohols under hydrogen pressure. This reduction is complementary to LiAlH₄-mediated amide reduction. Most likely, an aromatization/dearomatization sequence of the heterocycle occurs, thus constituting the microscopic reverse of the amide synthesis discussed above (cf Scheme 2). The possibility to switch the reactivity from dehydrogenation (amide synthesis)
to hydrogenation (amide cleavage) by changing the reaction atmosphere illustrates the robustness of the pincer metal unit in these transformations.

C–O bond activation

The cleavage of C–O bonds has been demonstrated in stoichiometric and catalytic processes. Stoichiometric Caryl–O bond scission occurs upon heating the pincer ligand precursor 36a in the presence of [RhCl(ethene)2] (Scheme 14).48 The PCP rhodium complex 37 is formed along with formaldehyde, and no activation of the less strong Calkyl–O bond has been observed. Most conceivably, this high chemoselectivity is due to a mechanism that is related to Caryl–Calkyl bond cleavage (cf. Schemes 10 and 11), involving a P,P-bidentate coordination of 36a and subsequent formation of an (aryl)(methoxy) rhodium(III) intermediate that may undergo facile elimination and extrusion of formaldehyde. Mutually transoid bidentate coordination of the phosphines appears to be an essential factor for directing the metal center to the Caryl–O rather than the Calkyl–O bond. With related monophosphine ligand precursors, cleavage of the weaker Calkyl–O bond has been observed. Furthermore, bulky Bu-substituents at the phosphorus give better results than phenyl groups.

Scheme 14. Rhodium- and palladium-mediated C–O cleavage within a pincer scaffold.

With harder and more electrophilic palladium(II) and nickel(II) centers, Lewis acid-base complexation to oxygen becomes more relevant, and consequently, Calkyl–O bond activation as in monophosphine ligands is observed (38, Scheme 14).49,50 The bond cleavage selectivity is dependent on the substitution pattern at oxygen. Larger substituents decrease oxygen-metal interactions and accordingly, C–O activation in the ethoxy PCP ligand precursor 36b is less selective than in the methoxy analogue and results in both Caryl–O and Calkyl–O bond cleavage (9:1 ratio at 130 °C).

The ring strain imposed by the two six-membered metalacycles in complex 38 has been exploited to develop an oxygen transfer process reminiscent of the methylene transfer reaction in related complexes. Oxygen extrusion from 38 in the presence of H2 is achieved at high temperatures (180 °C) and yields the PCP palladium complex 39 and H2O. Similarly, the (aryl)(methoxy) rhodium(III) intermediate has been successfully employed for transferring an alkoxide. Upon performing the rhodation of the precursor 36a in the presence of MeSiH3, MeOSiEt3 has been obtained rather than formaldehyde along with complex 37. Catalytic C–O bond cleavage has been achieved with the cationic PCP iridium complex 40 in the presence of HSiEt3 (Scheme 15).51 A variety of primary, secondary, and tertiary ethers have been successfully cleaved at room temperature. Ethers with bulky alkyl groups undergo a single C–O cleavage and give one equivalent of alkane RH and the corresponding silyl ether ROSiEt3. More basic and less bulky ethers engage in two sequential C–O bond cleavage reactions and produce two equivalents of alkane RH along with Et2SiOSiEt3.

Mechanistic work suggests a process that involves reversible coordination of the silane to the iridium cation followed by hydride transfer from silicon to the iridium center, thus forming a silyl cation that is ether-stabilized. Subsequent C–O cleavage is promoted by the iridium dihydride intermediate, thus yielding the silyl ether and the alkane, and also regenerating the cationic complex 40. This step is rate-limiting. The oxonium species 41 as the catalyst resting state along with the known dihydride 42 has been isolated and characterized crystallographically. With less basic ethers than Et2O, the resting state shifts forward from the oxonium salt to the silane complex T, which is also relevant to the iridium-catalyzed dehalogenation of alkyl halides.52

Conversion of CO and CO2 has been probed with a variety of pincer metal complexes, motivated at least in parts by the environmental relevance of these small molecules. The rhodium dihydride complex 43 inserts dry CO2 into the Rh–H bond and yields a PCP rhodium complex containing a formate ligand, corresponding to a formal reduction of CO2 (Scheme 16).53 The stability of the formate intermediate is strongly dependent on the nature of the metal center and on the type of pincer ligand. Changing the metal center in complex 43 to iridium affords the less stable formate complex 44 which disproportionates to a bicarbonate and a carbonyl iridium complex.54 Similarly, modification of the anionic fragment...
from an alkyl moiety to an aryl anion (complex 45) transforms the formate complex into a transient, yet spectroscopically detectable intermediate that spontaneously eliminates H₂O to yield a rhodium(I) carbonyl complex. Formally, this process involves the reduction of CO₂ to CO and thus constitutes the reverse of the water-gas shift reaction. The stoichiometric oxidation of CO to CO₂ has been achieved with the platinum(IV) oxo complex 46. Concomitant reduction of the metal center affords a cationic PCN platinum(II) complex containing a carbonyl ligand. A C-bound formate complex has been obtained upon reaction of the platinum complex 47 with NaOMe. Hence formate fragments may be assembled either from CO₂ or from CO.

\[ \text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{CO} + \text{H}_2 \text{O} \]

\[ \text{CO}_2 + \text{NaOMe} \rightarrow \text{CO} + \text{MeONa} \]

Scheme 16. Reactivity of pincer complexes towards CO₂ and CO.

C–F bond activation

The chemistry of the C–F bond is of high relevance, in particular for pharmaceutical applications. The bond is considered to be one of the strongest bonds and methods for C–F bond formation and scission are thus of paramount interest. Cleavage of the C–F bond has been reported in a PNP titanium complex comprising a Schrock-type carbene ligand. With fluoroarenes such as C₆H₅F, the C–H bond is activated selectively. Upon warming to 100 °C, C–F bond cleavage occurs via β-fluoride abstraction, resulting in a PNP–TiF complex and ortho-benzylene as side product, which has been identified by trapping experiments.

\[ \text{C}_6\text{H}_5\text{F} + \text{Ti} \text{F}_4 \rightarrow \text{C}_6\text{H}_5\text{F}^+ \text{TiF}_3 + \text{H}_2 \text{F}_2 \]

\[ \text{C}_6\text{H}_5\text{F} + \text{H}_2\text{O} \rightarrow \text{C}_6\text{H}_5\text{OH} + \text{HF} \]

Scheme 17. C–F bond cleavage by a PCP platinum(0) complex.

Activation of E–H bonds

N–H bond activation

A PCP iridium pincer complex comprising an aliphatic carbonic moiety has been successfully employed for the activation of ammonia and hydrazine. While only stoichiometric activation has been achieved, interesting transfer reactions may emerge from metal bound amides.

Related work has demonstrated the stoichiometric activation of a N–H bond of various anilines mediated by complex 3 (cf Table 1). Ligand participation via heterocycle aromatization may be a key feature also in this activation process.

O–H bond activation

Activation of the O–H bond in alcohols has been invoked in the activation of H₂ at the PNP iridium(I) complex 14b (cf Fig 2). The formation of the trans dihydride oxidative addition product implies an indirect activation process, presumably including first RO–H bond activation to form complex 15b as a transient intermediate with RO⁻ as counterion. Subsequent heterolytic H₂ activation regenerates the alcohol, albeit with a proton stemming from H₂. Rapid incorporation of deuterium upon performing the reaction in the presence of D₂O or CD₃OD support the postulated reaction pathway. Ligand assisted RO–H bond activation has been observed also in PNP platinum and palladium complexes, in which the PNP ligand is dearomatized. In this case, the hydrogen is ultimately bound to the benzylic position, inducing aromatization of the heterocycle. The activity of this type of pincer complexes towards O–H bond activation has been further expanded to develop a process that allows for effective water splitting at complex 4 (Scheme 18). The reaction includes cooperative fixation of water at the ruthenium center and the pincer ligand to give complex 50, followed by thermally induced H₂ elimination, affording the dihydroxide. Consecutive light-induced dissociation of H₂O₂ and disproportionation yields O₂ and H₂O. Intramolecular hydrogen transfer from the benzylic position of intermediate U to the ruthenium center and concomitant de-aromatization regenerates complex 4. Isotope labeling experiments have demonstrated that the H₂O₂ formation is an intramolecular process.

\[ \text{H}_2\text{O} + \text{H}_2\text{O}_2 \rightarrow \text{H}_2 \text{O} + \text{H}_2 \text{O}_2 \]

\[ \text{H}_2 \text{O} + \text{H}_2 \text{O}_2 \rightarrow \text{H}_2 \text{O} + \text{H}_2 \text{O}_2 \]

\[ \text{U} + \text{H}_2 \text{O}_2 \rightarrow \text{V} + \text{H}_2 \text{O} \]

\[ \text{V} + \text{H}_2 \text{O} \rightarrow \text{U} + \text{H}_2 \text{O}_2 \]

\[ \text{U} + \text{H}_2 \text{O}_2 \rightarrow \text{V} + \text{H}_2 \text{O} \]
process rather than a consequence of a bimolecular reaction. Even though parts of the water splitting need to be sequentially pulsed by thermal and photochemical stimulation, the possibility to split water at a single metal center provides intriguing perspectives for further developments.

**Si–H bond activation**

Catalytic Si–H bond activation using the PCP iridium complexes 40 and 42 has been discussed together with C–O bond activation in ethers (cf Scheme 15). The same mechanism of silane activation has been exploited for the catalytic reduction of alkyl halides. Elegant competition experiments have uncovered a pre-equilibrium involving iridium coordination either to RX or to HSiEt₂. This equilibrium is responsible for the unusual preference of catalyst 40 to convert pure RBr faster than pure RCl and much faster than RI. In mixtures, however, the expected reactivity sequence RI > RBr > RCl is restored, as the pre-equilibrium is shifted to HSiEt₂ coordination when the better coordinating iodoalkane is present only in minor quantities. Both intra- and intermolecular Si–H activation has been observed at a platinum center bound to a PSiP pincer ligand. Mechanistic studies may unravel intriguing differences between Si–H bond activation processes and the well-understood C–H bond activation.

**Conclusions**

Pincer ligands have provided an excellent platform for tailoring the activity of metal centers towards the cleavage of strong bonds that are typically unreactive. Both stoichiometric metal-mediated reactions as well as efficient pincer metal-catalyzed processes have been disclosed, many of which lacking precedence such as room temperature C–C bond making and breaking and the complete splitting of water at a single metal center. The high steric and electronic flexibility of the pincer ligand has been pivotal for uncovering mechanistic details that also provide guidelines for general transition metal-mediated reactions. Furthermore, pincer ligands show great potential to adapt to specific needs of the coordinated metal center, as illustrated for example by reversible ligand de- and re-aromatization, and by the accommodation of metals in various oxidation states (cf platinum(0) up to platinum(IV) within the same PCP pincer scaffold). Despite the remarkable progress achieved up to now, the enormous variability in pincer chemistry—from through modification of the donor groups as well as in the central unit—may pave the way for further breakthroughs in bond activation processes, thus providing exciting perspectives for organometallic chemistry, organic synthesis, and materials science.

Cleavage of unreactive bonds with pincer metal complexes

Martin Albrecht* and Monika M. Lindner

Due to the unique flexibility and tunability of pincer ligands, organometallic pincer complexes have been successfully employed for mediating and often also catalyzing the cleavage of typically unreactive bonds,
