INTRODUCTION

The end of the Triassic marked the beginning of a period of geological and ecological upheaval known as the Triassic–Jurassic mass extinction event (approx. 200 Mya). Although several studies have questioned the high rates (Hallam, 2002; Tanner et al., 2004) and sources (Bambach et al., 2004) of biodiversity loss across the Triassic–Jurassic boundary (TJB), it is widely considered as the third greatest mass extinction in the Phanerozoic (last approx. 450 million years) (Benton, 1995; McElwain and Punyasena, 2007). Plant communities were severely affected in terms of species turnover rates (Harris, 1937; Visscher and Brugman, 1981; Fowel et al., 1994; McElwain et al., 1999, 2007, 2009; Olsen et al., 2002) and evenness (i.e. the equality of relative abundances among taxa, McElwain et al., 2007, 2009), yet the available data suggest that higher taxonomic ranks displayed remarkable resilience (Ash, 1986; McElwain et al., 2007; Willis and McElwain, 2013). In general there is a negligible impact of mass extinctions on plants at the family level (Ash, 1986; McElwain et al., 2007; McElwain and Punyasena, 2007). Instead, plant communities undergo structural reformation, which includes substantial changes of families’ relative abundances and distributions and/or in some cases the total loss of growth habits (McElwain et al., 2007, 2009; McElwain and Punyasena, 2007; Bonis and Kuerschner, 2012). In this context, differences in the physiological plasticity between species, families or reproductive groups are expected to play a role in shaping the composition of plant communities under changing environmental conditions.

The causal mechanism of the TJB mass extinction has been actively debated (Hallam, 1997; McElwain et al., 1999, 2009; Palfy et al., 2001; Beerling and Berner, 2002; Hesselbo et al., 2002; Olsen et al., 2002; Marzoli et al., 2004). The organic carbon isotope record revealed a major, and synchronous with the mass extinction event, perturbation of the global carbon cycle in the form of a light carbon excursion across the TJB.

**Background and Aims** Fluctuations in [CO\text subscript{2}] have been widely studied as a potential driver of plant evolution; however, the role of a fluctuating [O\textsubscript{2}]:[CO\textsubscript{2}] ratio is often overlooked. The present study aimed to investigate the inherent physiological plasticity of early diverging, extant species following acclimation to an atmosphere similar to that across the Triassic–Jurassic mass extinction interval (TJB, approx. 200 Mya), a time of major ecological change.

**Methods** Mature plants from two angiosperm (Drimys winteri and Chloranthus oldhamii), two monilophyte (Osmunda claytoniana and Cyathus australis) and one gymnosperm (Ginkgo biloba) species were grown for 2 months in replicated walk-in Conviron BDW40 chambers running at TJB treatment conditions of 16 % [O\textsubscript{2}]-1900 ppm [CO\textsubscript{2}] and ambient conditions of 21 % [O\textsubscript{2}]-400 ppm [CO\textsubscript{2}]. They were grown in the form of a light carbon excursion across the TJB and their physiological plasticity was assessed using gas exchange and chlorophyll fluorescence methods.

**Key Results** TJB acclimation caused significant reductions in the maximum rate of carboxylation (V\text subscript{Cmax}) and the maximum electron flow supporting ribulose-1,5-bisphosphate regeneration (J\text subscript{max} in all species, yet this downregulation had little effect on their light-saturated photosynthetic rate (A\text subscript{sat}). Ginkgo was found to photosynthesize heavily under ambient conditions, while growth in low [O\textsubscript{2}]:[CO\textsubscript{2}] resulted in increased heat dissipation per reaction centre (DI/JRC), severe photodamage, as revealed by the species’ decreased maximum efficiency of primary photochemistry (F\textsubscript{v}/F\textsubscript{m}) and decreased in situ photosynthetic electron flow (J\text subscript{sat}).

**Conclusions** It is argued that the observed photodamage reflects the inability of Ginkgo to divert excess photosynthetic electron flow to sinks other than the downregulated C\text subscript{3} and the diminished C\text subscript{2} cycles under low [O\textsubscript{2}]:[CO\textsubscript{2}]. This finding, coupled with the remarkable physiological plasticity of the ferns, provides insights into the underlying mechanism of Ginkgoales’ near extinction and ferns’ proliferation as atmospheric [CO\textsubscript{2}] increased to maximum levels across the TJB.

**Key words:** Triassic–Jurassic boundary, Ginkgo biloba, gymnosperms, monilophytes, angiosperms, high CO\textsubscript{2}, low O\textsubscript{2}, photosynthetic plasticity, photorespiration, photodamage, stomatal conductance, mesophyll conductance.
MATERIALS AND METHODS

Plant material

Mature plants from five species belonging to some of the most early diverging families within each major reproductive grade (Supplementary Data Table S1), namely the monilophytes Osmunda claytoniana L. and Cyathea australis (R. Brown) Domin, 1929, the gymnosperm, ‘living fossil’ Ginkgo biloba L., and the angiosperm species Drimys winteri J.R. Forst. & G. Forst and Chloranthus oldhamii Solms were purchased, repotted and then acclimated to glasshouse conditions (mean temperature = 18°C) at University College Dublin Rosemount Environmental Research Station glasshouses for approx. 2 weeks. Pot size, soil mixture, type and amount of fertilizer used were determined independently based on the size, age and special preferences of each species (Table S1).
A trial study to assess potential ‘chamber effects’ was conducted prior to the initiation of growth chamber experiments (Porter et al., 2015). The study revealed that some of the eight Conviron BDW40 (Winnipeg, Manitoba, Canada) walk-in growth chambers of University College Dublin’s PEAC facility (Rosemount, University College Dublin) display significant ‘chamber effects’, thus their further use in the present study was avoided. Following the 2 week acclimation under glasshouse conditions, 2–3 fully expanded leaves were tagged on each individual and the plants were then transferred into four BDW40 growth chambers that displayed no chamber effects (see Porter et al., 2015). Half of the plants were subjected to a replicated TJB atmospheric treatment in two of the chambers for 2 months, while the rest were grown under ambient atmospheric conditions for the same amount of time, serving as our controls (Supplementary Data Table S2). The atmospheric composition used for the TJB treatment was 16% O₂ and 1900 ppm CO₂, which is a good approximation of the corresponding mean values for atmospheric O₂ and CO₂ across the boundary reported by mass balance modelling and palaeo-proxy studies (McElwain et al., 1999; Berner, 2001, 2006; Bergman et al., 2004; Belcher and McElwain, 2008; Bonis et al., 2010; Steinthorsdottir et al., 2011). The O₂ and CO₂ concentrations used for the ambient treatment were 21% and 400 ppm, respectively (Table S1).

CO₂ in each chamber was monitored by a WMA-4 infrared analyser (PP-Systems, Amesbury, MA, USA), and injection of compressed CO₂ (BOC Gases Ireland Ltd, Bluebell, County Dublin, Ireland) enabled stable within-chamber CO₂ concentrations well above ambient levels. The O₂ concentration in each chamber was monitored by a PP-systems OP-1 oxygen sensor, and injection of compressed N₂ produced by a nitrogen generator (Dalco Engineering, Dunshaughlin, County Meath, Ireland) was used to reduce the O₂ levels below ambient. The rest of the growth conditions were kept constant between the two treatments. All plants were grown under a 16h/8h simulated day/night program; 05:00–06:00 h, dawn; 06:00–09:00 h, light intensity progressively rises from 300 to 600 μmol m⁻² s⁻¹; 09:00–17:00 h, mid-day light intensity of 600 μmol m⁻² s⁻¹; 17:00–20:00 h, light intensity decreases from 600 to 300 μmol m⁻² s⁻¹; 20:00–21:00 h, dusk. Temperature ranged from a nighttime low of 15°C to a mid-day high of 20°C, and relative humidity was kept constant throughout the day at 65%. Chamber conditions in all chambers were recorded at 5 min intervals and are summarized in Table S2. Plants were watered regularly, receiving amounts of water which depended on the particular needs of each species under the two separate growth regimes. Upon completion of the 2 month treatment period, chlorophyll fluorescence and gas exchange measurements were performed on one of the tagged leaves of each plant. Measuring leaves that were fully expanded before the initiation of the treatments meant that we were able to exclude the effects of the simulated TJB atmosphere on the morphology of developing leaves (e.g. adaptation of stomatal density, stomatal index, leaf expansion, etc.). Consequently, our experimental approach enabled us to focus on differences in the innate plasticity/adaptability of the photosynthetic physiology, and specifically the ability to re-adjust the energy flows in the photosynthetic apparatus efficiently, among our test species after exposure to a low [O₂]:[CO₂] air mixture.

Gas exchange measurements

Upon completion of the 2 month acclimation period, the responses of net assimilation rate to incident light (light curves) and intercellular CO₂ partial pressure (A–Ci curves) were recorded within the chambers with a CIRAS-2 gas analyser (PP-Systems) attached to a PLC6(U) cuvette fitted with a 4.5 cm² measurement window and a red/white light LED unit. Theoretically, measuring within the TJB chambers at 16% O₂ could introduce error in our measurements due to broadening effects; however, it has been shown that these effects are negligible even when using O₂-free air (Loriaux and Welles, 2004). Measurements were performed on intact leaves between 09:00 and 12:00 h to avoid potential mid-day stomatal closure. Air flow, leaf temperature and vapour pressure deficit during both the light and A–Ci curves were maintained at 300 cm³ min⁻¹, 20°C and 1.0 ± 0.2 kPa, respectively.

For the light response curves, tagged leaves from 3–4 plants per species and treatment were enclosed in the cuvette and illuminated at either 1200 (O. claytoniana, C. australis and C. old- amii) or 1600 (G. biloba and D. winteri) μmol m⁻² s⁻¹ until full photosynthetic induction, as judged from three consecutive stable readings of CO₂ assimilation (A) and stomatal conductance (gₛ), usually within 30 min. The CO₂ and O₂ concentrations used were identical to the corresponding growth values for each treatment (ambient, 21% O₂–400 ppm CO₂; TJB, 16% O₂–1900 ppm CO₂). Light levels were then adjusted from 1200/1600 to 20 μmol m⁻² s⁻² in nine/ten descending steps, each with a 3 min duration, which was always adequate to obtain stable A readings. The light-saturated photosynthetic rate (A_sat) and saturating light intensity were then calculated according to Norman et al. (1992).

For the A–Ci curves, the tagged leaves previously used to acquire photosynthetic light response curves were again enclosed in the cuvette and allowed to equilibrate at 400 ppm CO₂, growth O₂ concentration (ambient, 21% O₂; TJB, 16% O₂) and saturating light intensity (calculated from the light response curves) for 30 min. CO₂ concentration in the cuvette (C_o) was then stepwise decreased from 400 to 50 μmol mol⁻¹ (400, 300, 200, 150, 100 and 50) and then increased from 50 to 2000 μmol mol⁻¹ (50, 400, 500, 600, 800, 1000, 1200, 1600 and 2000). Relative stability of C_o and A values at each step typically took 4 min, while a close agreement between the two measurements taken at 400 μmol mol⁻¹ indicated that exposure to low C_o had not affected the activation state of Rubisco (von Caemmerer and Edmondson, 1986; Ethier and Livingston, 2004). The resultants response curves were fitted using the model equations of Long and Bernacchi (2003). Implementation of the model allowed the calculation of the maximum Rubisco-limited rate of carboxylation (V_Cmax) and the maximum electron flow rate supporting RuBP regeneration (J_max). Respiration in the light (R_d) was also calculated as the y-axis intercept of the A–Ci response curve. We have to note here that the V_Cmax and J_max values reported in our study are adjusted at 25°C using the temperature functions of Bernacchi et al. (2001, 2003). A–Ci curves obtained using dried leaves of each species were used to...
correct all measurements for CO₂ leakages (Long and Bernacchi, 2003; Muir et al., 2014).

Incident growth light intensity (Q) for each species was measured with an MQ-200 quantum sensor (Apogee Instruments, Inc., Logan, UT, USA) and was then used to calculate the in situ electron transport rates from the non-rectangular hyperbola that describes the relationship between photon flux and electron transport (von Caemmerer, 2000) as:

\[
J_{\text{in situ}} = \frac{Q_z + J_{\text{max}} - \sqrt{(Q_z + J_{\text{max}})^2 - 4Q_zJ_{\text{max}}}}{2\theta}
\]  

(1)

where \( \theta \) is an empirical curvature factor with an average value of 0.7 (Evans, 1989), \( J_{\text{max}} \) is the maximum electron transport supporting RuBP regeneration and \( Q_z \) is the light utilized by photosystem II (PSII) and is calculated as:

\[
Q_z = Q \times \text{abs} \times \phi_{\text{PSIImax}} \times 0 \cdot 5
\]  

(2)

(Long and Bernacchi, 2003) where \( Q \) is the incident photosynthetically active radiation, \( \text{abs} \) is the leaf absorptance and \( \phi_{\text{PSIImax}} \) is the maximum efficiency of primary photochemistry. A common absorptance value of 0.85 was used in our calculations (von Caemmerer, 2000), and \( \phi_{\text{PSIImax}} \), which is equivalent to \( F_{v}/F_{m} \), was measured with a continuous excitation fluorimeter (see below). Average values of \( Q, F_{v}/F_{m} \) and \( J_{\text{max}} \) were used for the calculation of \( J_{\text{in situ}} \) at the species and treatment level.

In situ rates of ribulose 1,5-bisphosphate (RuBP) oxygenation (\( V_O \)) and carboxylation (\( V_C \)) were calculated from the corresponding light curve recordings (i.e. the step of the light curve with an intensity close to that received by each species in situ) according to Sharkey (1988) as:

\[
V_O = \frac{(A + R_d)}{(1/\varphi - 0 \cdot 5)}
\]  

(3)

\[
V_C = A + 0 \cdot 5 \times V_O + R_d
\]  

(4)

\[
\varphi = 2 \times \Gamma^*/C_c
\]  

(5)

Chloroplastic CO₂ concentrations (\( C_c \)) were calculated from the corresponding \( C_1 \) values as:

\[
C_c = C_1 - A/g_m
\]  

(6)

Mesophyll conductance (\( g_m \)) was calculated using the constant \( J \) modelling method of Harley et al. (1992). Five measurements of the RuBP regeneration-limited phase (typically at \( C_1 \) values between 50 and 120 Pa) of each \( A-C_1 \) response curve were used to calculate the photosynthetic linear electron flow rate (\( J \)) as:

\[
J = (A + R_d) \times \frac{[4 \times (C_1 - A/g_m) + 2 \times \Gamma^*]}{(C_1 - A/g_m) - \Gamma^*}
\]  

(7)

Given that \( J \) is constant when \( A \) is limited by the regeneration rate of RuBP, the \( g_m \) value that minimizes the variance in \( J \) was calculated iteratively using the Solver Microsoft Excel add-in (Warren, 2006).

\( \Gamma^* \) is the photosynthetic compensation point (i.e. the chloroplastic CO₂ concentration at which photosynthesis equals photorespiration) and depends on the temperature-sensitive relative affinity of Rubisco for CO₂ and O₂. \( \Gamma^* \) is considered to be relatively conserved among C₃ species and is linearly correlated with O₂ concentration; thus, we assigned standard values of 3-16/2-41 Pa at 20 °C and 21 %/16 % O₂, respectively, for all five species in our study (Bernacchi et al., 2002).

Chlorophyll fluorescence measurements

Chlorophyll fluorescence measurements were performed on all three tagged leaves of each plant for a total of 12–18 measurements per species and treatment. After dark-adapting the leaves for 1 h, a Pocket-Pea continuous excitation fluorimeter (Hansatech Instruments Ltd, Kings’ Lynn, Norfolk, UK) was used to capture their fast chlorophyll a fluorescence transients. Saturating light (approx. 3500 µmol m⁻² s⁻¹) was provided by a single high intensity red LED (peak at 627 nm), and chlorophyll fluorescence values were recorded from 10 µs to 1 s. Data acquisition rates were 10⁵, 10⁴, 10³, 10² and 10 readings per second in the time intervals of 10–300 µs, 0.3–3 ms, 3–30 ms, 30–300 ms and 0.3–1 s, respectively. The cardinal points of the recorded polyphasic fluorescence kinetics (OJIP curves, cardinal points: fluorescence value at 20 µs (\( F_o \)), fluorescence value at 300 µs (\( F_{300} \)), fluorescence value at 2 ms (\( F_i \)), fluorescence value at 30 ms (\( F_j \) and maximal fluorescence intensity (\( F_m \))) were then used to derive the following parameters according to the JIP-test (Strasser et al., 2004), as extended to include the effect of events related to the final electron acceptors of PSI (Tsimilli-Michael and Strasser, 2008):

\[
(1) \quad F_{o}/F_m = (F_m - F_o)/F_m \text{ or maximum quantum yield of primary photochemistry.}
\]

\[
(2) \quad DI_{RC} = (ABS/RC) - (TR_{RC}) \text{ is the heat dissipation per reaction centre at time zero.}
\]

where:

\[
ABS/RC = M_r/V_i \text{ is the absorption energy flux per PSII reaction centre.}
\]

\[
TR_{RC} = M_r/V_i \text{ is the trapping per reaction centre at time zero.}
\]

\[
M_r = 4 \times \left( F_{300} - F_o \right) / \left( F_m - F_o \right) \text{ is the slope at the origin of the fluorescence rise.}
\]

\[
V_i = \left( F_{300} - F_o \right) / F_{300} \text{ is the relative variable fluorescence at 2 ms.}
\]

Statistical analysis

Statistical analysis was performed in R (v.3.1.1). Data were tested for normality and equal variance, and analysed using mixed effects models. Chamber identity was treated as a random effect to identify a possible chamber effect (no chamber effect was detected). Multiple models were run with random and interaction effects. Models were compared using analysis of variance (ANOVA) comparison, and the best fit model was determined using the Akaike information criterion (AIC).
One-way ANOVA and Tuckey post-hoc analysis were performed to assess the significance level of the differences between all fixed effects (i.e. species and treatments) from the best fit model.

RESULTS

Light response curves indicated that the $A_{sat}$ of the test species did not acclimate uniformly to low $[O_2]:[CO_2]$ (Fig. 1). Even though the photosynthetic stimulation was statistically significant only in C. oldhamii, the two ferns and the two angiosperms increased their $A_{sat}$ by 13-6–43.0 % depending on the species, while the gymnosperm G. biloba displayed a small, non-significant decrease (6-1 %). We should note here that Ginkgo exhibited a decrease in its light-saturated photosynthetic rate despite the fact that light curves for all species were taken at growth CO$_2$ concentration, i.e. nearly 5-fold higher CO$_2$ concentration for the TJB treatment plants compared with controls.

This first sign of photosynthetic downregulation under low $[O_2]:[CO_2]$ was confirmed by the results of the A–C$_i$ curves (Table 1). Acclimation to low $[O_2]:[CO_2]$ led to significant decreases in $V_{Cmax}$ and to a lesser extent $J_{max}$ values in all test species; however, the decreases were most prominent in G. biloba, reaching 64.8 and 57.8 %, respectively, relative to the corresponding values of the control plants (Table 1). As a result of these changes, almost all species exhibited a decreased mean $V_{Cmax}/J_{max}$ ratio under low $[O_2]:[CO_2]$ (Table 1), which is indicative of an altered balance between RuBP carboxylation and regeneration typically observed in plants growing at high CO$_2$ (Long et al., 2004; Ainsworth and Rogers, 2007; Osada et al., 2010). Yet, we should note that only in three of the species was this decrease statistically significant.

In situ carboxylation rates ($V_C$) did not display significant changes, despite the decrease in $V_{Cmax}$, due to the much higher growth CO$_2$ concentration of the TJB treatment (Table 1). As expected, in situ oxygenation rates of Rubisco ($V_O$) diminished due to the very low $[O_2]:[CO_2]$ ratio of the growth air mixture in combination with the altered absolute concentrations of both gases (Table 1), yet overall G. biloba was the only species to display a significantly decreased combined rate of Rubisco carboxylation/oxygenation under TJB atmospheric conditions ($V_C + V_O$, Table 1). Furthermore, G. biloba was also the species that displayed the most significant reductions in absolute ($V_O$) and relative ($V_O/V_C$) rates of oxygenation primarily as a result of its extraordinarily high rates of Rubisco oxygenation under ambient conditions (Table 1). Indeed, calculation of the total conductance ($g_l$) from the measured values of $g_s$ and $g_m$ revealed that under ambient atmospheric CO$_2$, G. biloba poses substantially higher resistances to CO$_2$ diffusion and its photosynthetic machinery operates under significantly lower $C_c$ compared with the rest of the test species (Fig. 2A, B).

Ribulose-1,5-bisphosphate is the substrate for both carboxylation and oxygenation reactions of Rubisco, thus the reduction of the combined Rubisco carboxylation/oxygenation rate observed in the TJB treatment Ginkgo plants should normally be accompanied by a proportional reduction in the in situ rates of electron transport supporting RuBP regeneration ($J_{situ}$). Indeed, $J_{situ}$ values followed a similar pattern, showing small, non-significant changes between control and TJB plants in ferns and C. oldhamii, moderate decrease in D. winteri, a substantial decrease in G. biloba (Table 1) and correlated with the corresponding decreases in $V_C + V_O$ (Fig. 3A). It is interesting, however, that when the relatively small changes in $V_C$ values are ignored and the changes in $J_{situ}$ are plotted against the corresponding changes in $V_O$, the correlation becomes more robust (Fig. 3B). In addition, there also seems to be good correlation between the relative decreases in the in situ $V_O$ [Rel. $DV_O =$ ($V_{Oamb} - V_{OTJB}$)/$V_{Oamb}$] and the decreases of Rubisco content-dependent $V_{Cmax}$ when plants are exposed to the TJB atmospheric treatment (Fig. 4).

Exposure to the TJB treatment led to plant group-specific changes in $F_v/F_m$ (Fig. 5A). Compared with controls, the two fern species maintained high $F_v/F_m$ values while angiosperms showed moderate, yet non-significant decreases. Ginkgo biloba was the only species to display a substantial drop in its $F_v/F_m$, which indicated that low $[O_2]:[CO_2]$ acclimation resulted in partial photoinhibition. Interestingly, changes in $F_v/F_m$ were found to correlate linearly with changes in both $J_{situ}$ and $V_O$ (Fig. 6A, B). Furthermore, in the case of G. biloba, the substantial decrease in the maximum quantum yield of primary photochemistry was accompanied by a 2.5-fold increase in the rate of heat dissipation per PSII reaction centre (DI/RRC) (Fig. 5B). This clearly suggested a severely decreased efficiency of photosynthetic light reactions in the low $[O_2]:[CO_2]$-acclimated plants.

DISCUSSION

Our results clearly demonstrate that Ginkgo biloba diverts an extraordinarily high percentage of the ATP and NADPH produced during the photosynthetic light reactions to photosynthetic metabolism when grown under ambient CO$_2$ and O$_2$ concentrations (Table 1). This is contrary to the pattern observed in the two fern and two angiosperm species studied. Inherent (Yiotis et al., 2010) as well as stress-induced (Flexas et al., 2014)
Table 1. $V_{\text{Cmax}}, J_{\text{max}}, V_{\text{Cmax}}/J_{\text{max}}$ ratio, $V_{\text{C}}, V_{\text{O}}, V_{\text{C}} + V_{\text{O}}, V_{\text{O}}/V_{\text{C}}$ ratio and $J_{\text{situ}}$ of the species under ambient (400 ppm CO$_2$, 21 % O$_2$) and TJB (1900 ppm CO$_2$, 16 % O$_2$) atmospheric conditions

$V_{\text{Cmax}}$, maximum carboxylation rate (25 °C); $J_{\text{max}}$, maximum electron rate supporting RuBP regeneration (25 °C); $V_{\text{C}}$, in situ carboxylation rate; $V_{\text{O}}$, in situ oxygenation rate; $V_{\text{C}} + V_{\text{O}}$, combined oxygenation/carboxylation rate; $J_{\text{situ}}$, in situ electron transport rate. Values are means ± s.d.; n = 3–4 depending on species. Different letters for each species denote statistically significant differences between treatments ($P \leq 0.05$).
biochemical restrictions limiting the $g_o$ and $g_m$ of G. biloba, the species could still increase its operational $C_c$ by photosynthesizing at lower rates. Since the light-saturated photosynthesis of G. biloba is clearly limited by its Rubisco carboxylation capacity, a reduction in the enzyme’s content could facilitate an increase in the operational $C_c$ values. It is apparent that such a reallocation of nitrogen from Rubisco to other proteins would decrease the relative photosynthetic carbon losses under low [CO$_2$]. Although photosynthesis was initially considered a wasteful evolutionary relic resulting from a lack of selective pressure when Rubisco was selected by photosynthetic bacteria as their primary carboxylase, recent evidence has demonstrated the importance of photorespiration in photoprotection (Osmond and Grace, 1995; Kozaki and Takeba, 1996; Niyogi, 2000; Takahashi et al., 2007) and nitrogen assimilation (Somerville and Ogren, 1980; Rachmilevitch et al., 2004; Heldt, 2005; Bloom et al., 2010; Bloom, 2015). Interestingly, our results show that there is good correlation between the decreases in $V_O$ and the Rubisco content-dependent $V_{C_{\text{max}}}$ (Fig. 4). Moreover, due to the sheer amount of leaf nitrogen invested in Rubisco (Evans, 1989), we could argue that $V_{C_{\text{max}}}$ generally reflects plant nitrogen content and nitrogen assimilation capacity (Walker et al., 2014). Concomitantly, the correlation between the relative decreases in $V_O$ and $V_{C_{\text{max}}}$ seems to support the proposed link between photorespiration and nitrogen assimilation.

Plants have a complex control mechanism that adjusts the rate of the ‘light photosynthetic reactions’ and the combined rate of photosynthesis and photorespiration so that they match each other (Sharkey, 1990; Zhang and Portis, 1999; Andersson, 2008; Parry et al., 2008); however, stress conditions can slow down the rate of the Calvin-Benson-Bassham cycle, thus generating a potentially harmful imbalance. In these cases, photorespiration is believed to act as a safety valve, quenching the excess absorbed light energy by consuming the produced ATP and NADPH that cannot be used for carbon assimilation. Exposure to a TJB treatment, however, diminished photorespiration (Table 1; Fig. 7) and in conjunction with the stable or decreased in situ $V_C$ (Table 1; Fig. 7) led to a drop in the demand for RuBP regeneration, which is reflected in the corresponding drops in operational $J_{\text{situ}}$ (Table 1; Figs. 3A, B and 7).

Under these conditions of reduced capacity for photosynthetic and photorespiratory quenching of absorbed light energy, the electron transport chain of the light reactions becomes over-reduced and plants are forced to increase the efficiency of energy quenching through heat dissipation in order to avoid permanent photodamage (Demmg-Adams and Adams, 1996; Horton et al., 1996; Müller et al., 2001; Lambrev et al., 2012). The amplitude of this increase depends on the amount of excess absorbed energy or, in our case, the drop in the capacity for photosynthetic and photorespiratory quenching, assuming no significant changes in leaf absorption. Indeed, under low [O$_2$]:[CO$_2$], G. biloba displayed the highest increase in the heat dissipation per reaction centre ($DI_o/RC$) compared with the rest

**Fig. 3.** (A) Relationship ($y = 7.35x - 1.03, r^2 = 0.82, P = 0.033$) between the observed changes in the combined in situ oxygenation/carboxylation rate ($DV_c + DV_o$) and the corresponding changes of the in situ electron transport rate supporting RuBP regeneration ($DV_{ma}$). Data are differences resulting after subtraction of the mean values of the ambient treatment (400 ppm CO$_2$, 21% O$_2$) from the corresponding values of the TJB (1900 ppm CO$_2$, 16% O$_2$) treatment. (B) Relationship ($y = 16.15x + 8.98, r^2 = 0.95, P = 0.005$) between the observed changes in the in situ oxygenation rate ($DV_O$) and the corresponding changes in the in situ electron transport rate supporting RuBP regeneration ($DV_{ma}$). Data are differences resulting after subtraction of the mean values of the ambient treatment (400 ppm CO$_2$, 21% O$_2$) from the corresponding values of the TJB (1900 ppm CO$_2$, 16% O$_2$) treatment.

**Fig. 4.** Relationship ($y = 244x + 192, r^2 = 0.95, P = 0.003$) between the relative observed changes in the in situ oxygenation rate [Rel. $DV_O = (V_{O_{amb}} - V_{OTJB})/V_{Oamb}$] and the corresponding changes in the maximum rate of carboxylation ($DV_{C_{\text{max}}}$). $DV_{C_{\text{max}}}$ data are differences resulting after subtraction of the mean values of the ambient treatment (400 ppm CO$_2$, 21% O$_2$) from the corresponding values of the TJB (1900 ppm CO$_2$, 16% O$_2$) treatment.
anced by the increased CO$_2$ concentration in such a way that exposure to a low [O$_2$]:[CO$_2$] atmosphere and subsequent stress and/or nitrogen assimilation capacity. Yet, it is apparent that ferns, angiosperms, and the TJB atmospheric conditions. Ferns' adaptability of electron flow severely affects the species' competitiveness, especially when compared with the fern species, which display a high level of photosynthetic plasticity. In contrast to G. biloba, ferns and angiosperms displayed a remarkable adaptability of their physiology to TJB atmospheric conditions. Ferns' adaptative decreases in $V_{C_{\text{max}}}$ and $J_{\text{max}}$ (Table 1) were counterbalanced by the increased CO$_2$ concentration in such a way that of the species, with ferns and angiosperms only showing negligible changes (Figs 5B and 7). Even so, it appears that the increased efficiency of heat dissipation is not adequate to alleviate photoinhibition, as revealed by the significant decrease of $F_v/F_m$ in G. biloba under TJB atmospheric conditions (Figs 5A, 6A, B and 7).

Our results do not allow us to identify the increased rate of photorespiration in G. biloba either as proof of the species’ reduced fitness to current low atmospheric CO$_2$ or as an evolutionary strategy aiming to enhance the species’ persistence to stress and/or nitrogen assimilation capacity. Yet, it is apparent that exposure to a low [O$_2$]:[CO$_2$] atmosphere and subsequent diminishment of the photorespiratory sink for photosynthetic electron flow severely affects the species’ competitiveness, especially when compared with the fern species, which display a high level of photosynthetic plasticity. In contrast to G. biloba, ferns and angiosperms displayed a remarkable adaptability of their physiology to TJB atmospheric conditions. Ferns’ adaptative decreases in $V_{C_{\text{max}}}$ and $J_{\text{max}}$ (Table 1) were counterbalanced by the increased CO$_2$ concentration in such a way that both the in situ $V_C$ and $A_{\text{sat}}$ showed an increasing, yet non-statistically significant, trend (Table 1; Fig. 1). In addition, the absence of changes in the heat dissipation per reaction centre ($D_{J_v}/RC$) and the maximum efficiency of primary photochemistry ($F_v/F_m$) under nearly non-photorespiratory conditions further highlights their ability to acclimate their physiology effectively to low [O$_2$]:[CO$_2$] (Figs 5A, B and 7).

We acknowledge that an increase in global temperature and high atmospheric CO$_2$-induced decreased transpiration of the broadleaved Ginkgoales must have played a role in their decline across the TJB (McElwain et al., 1999). However, the present work provides an additional mechanism that may have contributed to the near extinction of Ginkgoales and to the proliferation of ferns evident in the TJB fossil record (Fowell and Olsen, 1993; Olsen et al., 2002; McElwain et al., 2007). Our study focused exclusively on innate differences in the photosynthetic plasticity and did not investigate the anatomical
adaptations of leaves grown under a TJB atmosphere. Yet, we would like to note that after >100 million years of plant evolution and despite the plummeting of atmospheric CO₂ levels, gymnosperms still display relatively low values of stomatal and mesophyll conductance, even though higher values would have enabled them to maintain higher photosynthetic rates and/or higher photosynthetic nitrogen use efficiency (Flexas et al., 2012; McElwain et al., 2016). Based on this apparent reduced anatomical/physiological adaptability of gymnosperms, we believe that the responses of present-day G. biloba to a TJB treatment are likely to resemble those of Ginkgoales present during the TJB. Overall, our study stresses the importance of differences in the physiological plasticity of different plant groups in shaping evolutionary patterns under fluctuating atmospheric O₂ levels, we argue that further investigation of the in vivo temperature response functions for models of Rubisco-limited photosynthesis. Plant, Cell & Environment 24: 253–259.
